Identification of b-quark jets with the CMS experiment

The CMS Collaboration^{*}

Abstract

At the Large Hadron Collider, the identification of jets originating from b quarks is important for searches for new physics and for measurements of standard model processes. A variety of algorithms has been developed by CMS to select b-quark jets based on variables such as the impact parameters of charged-particle tracks, the properties of reconstructed decay vertices, and the presence or absence of a lepton, or combinations thereof. The performance of these algorithms has been measured using data from proton-proton collisions at the LHC and compared with expectations based on simulation. The data used in this study were recorded in 2011 at $\sqrt{s} = 7\text{ TeV}$ for a total integrated luminosity of 5.0 fb^{-1} . The efficiency for tagging b-quark jets has been measured in events from multijet and t-quark pair production. CMS has achieved a b-jet tagging efficiency of 85% for a light-parton misidentification probability of 10%. For analyses requiring higher purity, a misidentification probability of only 1.5% has been achieved, for a 70% b-jet tagging efficiency.

1 Introduction

Jets that arise from bottom-quark hadronization (b jets) are present in many physics processes, such as the decay of top quarks, the Higgs boson, and various new particles predicted by supersymmetric models. The ability to accurately identify b jets is crucial in reducing the otherwise overwhelming background to these channels from processes involving jets from gluons (g) and light-flavour quarks (u, d, s), and from c -quark fragmentation.

The properties of the bottom and, to a lesser extent, the charm hadrons can be used to identify the hadronic jets into which the b and c quarks fragment. These hadrons have relatively large masses, long lifetimes and daughter particles with hard momentum spectra. Their semileptonic decays can be exploited as well. The Compact Muon Solenoid (CMS) detector, with its precise charged-particle tracking and robust lepton identification systems, is well matched to the task of b -jet identification (b -jet tagging). The first physics results using b -jet tagging have been published [1–3] from the first data samples collected at the Large Hadron Collider (LHC).

This paper describes the b -jet tagging algorithms used by the CMS experiment and measurements of their performance. A description of the apparatus is given in Section 2. The event samples and simulation are discussed in Section 3. The algorithms for b -jet tagging are defined in Section 4. The distributions of the relevant observables are compared between simulation and proton-proton collision data collected in 2011 at a centre-of-mass energy of 7 TeV. The robustness of the algorithms with respect to running conditions, such as the alignment of the detector elements and the presence of additional collisions in the same bunch crossing (pileup), is also discussed.

Physics analyses using b -jet identification require the values of the efficiency and misidentification probability of the chosen algorithm, and, in general, these are a function of the transverse momentum (p_T) and pseudorapidity (η) of a jet. They can also depend on parameters such as the efficiency of the track reconstruction, the resolution of the reconstructed track parameters, or the track density in a jet. While the CMS simulation reproduces the performance of the detector to a high degree of precision, it is difficult to model all the parameters relevant for b -jet tagging. Therefore it is essential to measure the performance of the algorithms directly from data. These measurements are performed with jet samples that are enriched in b jets, either chosen by applying a discriminating variable on jets in multijet events or by selecting jets from top-quark decays. The methods that are used to measure the performance are described in Sections 5 and 6. The measurements are complementary: multijet events cover a wider range in p_T , while the results obtained from $t\bar{t}$ events are best suited for some studies of top-quark physics. The efficiency measurements are summarized and compared in Section 7. The measurement of the misidentification probability of light-parton (u, d, s, g) jets as b jets in the data is presented in Section 8.

2 The CMS detector

The central feature of the CMS apparatus is a superconducting solenoid, of 6 m internal diameter, which provides a magnetic field of 3.8 T. Within the field volume are the silicon tracker, the crystal electromagnetic calorimeter, and the brass/scintillator hadron calorimeter. Muons are measured in gas-ionization detectors embedded in the steel return yoke.

CMS uses a right-handed coordinate system, with the origin at the nominal interaction point, the x axis pointing to the centre of the LHC ring and the z axis along the counterclockwise-beam direction. The polar angle, θ , is measured from the positive z axis and the azimuthal angle, ϕ ,

is measured in the x - y plane. The pseudorapidity is defined as $\eta \equiv -\ln[\tan(\theta/2)]$. A more detailed description of the CMS detector can be found elsewhere [4].

The most relevant detector elements for the identification of b jets and the measurement of algorithm performance are the tracking system and the muon detectors. The inner tracker consists of 1440 silicon pixel and 15 148 silicon strip detector modules. It measures charged particles up to a pseudorapidity of $|\eta| < 2.5$. The pixel modules are arranged in three cylindrical layers in the central part of CMS and two endcap disks on each side of the interaction point. The silicon strip detector comprises two cylindrical barrel detectors with a total of 10 layers and two endcap systems with a total of 12 layers at each end of CMS. The tracking system provides an impact parameter (IP) resolution of about $15 \mu\text{m}$ at a p_{T} of $100 \text{ GeV}/c$. In comparison typical IP values for tracks from b-hadron decays are at the level of a few $100 \mu\text{m}$. Muons are measured and identified in detection layers that use three technologies: drift tubes, cathode-strip chambers, and resistive-plate chambers. The muon system covers the pseudorapidity range $|\eta| < 2.4$. The combination of the muon and tracking systems yields muon candidates of high purity with a p_{T} resolution between 1 and 5%, for p_{T} values up to $1 \text{ TeV}/c$.

3 Data samples and simulation

Samples of inclusive multijet events for the measurement of efficiencies and misidentification probabilities were collected using jet triggers with p_{T} thresholds of 30 to $300 \text{ GeV}/c$. For efficiency measurements, dedicated triggers were used to enrich the data sample with jets from semimuonic b-hadron decays. These triggers required the presence of at least two jets with p_{T} thresholds ranging from 20 to $110 \text{ GeV}/c$. One of these jets was required to include a muon with $p_{\text{T}} > 5 \text{ GeV}/c$ within a cone of $\Delta R = 0.4$ around the jet axis, where ΔR is defined as $\sqrt{(\Delta\phi)^2 + (\Delta\eta)^2}$. Triggers with low- p_{T} thresholds were prescaled in order to limit the overall trigger rates. Depending on the prescale applied to the trigger, the multijet analyses used datasets with integrated luminosities of up to 5.0 fb^{-1} .

Data for the analysis of $t\bar{t}$ events were collected with single- and double-lepton (e and μ) triggers. The samples were collected in the first part of the 2011 data taking with an integrated luminosity of 2.3 fb^{-1} . The precision on the b-jet tagging efficiency from $t\bar{t}$ events is limited by systematic uncertainties. Using the full dataset collected in 2011 would not reduce the overall uncertainty.

Monte Carlo (MC) simulated samples of multijet events were generated with PYTHIA 6.424 [5] using the Z2 tune [6]. For b-jet tagging efficiency studies, dedicated multijet samples have been produced with the explicit requirement of a muon in the final state.

In the simulation, a reconstructed jet is matched with a generated parton if the direction of the parton is within a cone of radius $\Delta R = 0.3$ around the jet axis. The jet is then assigned the flavour of the parton. Should more than one parton be matched to a given jet, the flavour assigned is that of the heaviest parton. The b flavour is given priority over the c flavour, which in turn is given priority over light partons. According to this definition jets originating from gluon splitting to $b\bar{b}$, which constitute an irreducible background for all tagging algorithms, are classified as b jets.

Events involving $t\bar{t}$ production were simulated using the MADGRAPH [7] event generator (v. 5.1.1.0), where the top quark pairs were generated with up to four additional partons in the final state. A top quark mass of $m_t = 172.5 \text{ GeV}/c^2$ was assumed. The parton configurations generated by MADGRAPH were processed with PYTHIA to provide showering of the

generated particles. The soft radiation was matched with the contributions from the matrix element computation using the k_T -MLM prescription [8]. The tau-lepton decays were handled with TAUOLA (v. 27.121.5) [9].

The electroweak production of single top quarks is considered as a background process for analyses using $t\bar{t}$ events, and was simulated using POWHEG 301 [10]. The production of W/Z + jets events, where the vector boson decays leptonically, has a signature similar to $t\bar{t}$ and constitutes the main background. These events were simulated using MADGRAPH +PYTHIA, with up to four additional partons in the final state. The bottom and charm components are separated from the light-parton components in the analysis by matching reconstructed jets to partons in the simulation.

Signal and background processes used in the analysis of $t\bar{t}$ events were normalized to next-to-leading-order (NLO) and next-to-next-to-leading-order (NNLO) cross sections, with the exception of the QCD background.

The top-quark pair production NLO cross section was calculated to be $\sigma_{t\bar{t}} = 157^{+23}_{-24}$ pb, using MCFM [11]. The uncertainty in this cross section includes the scale uncertainties, estimated by varying simultaneously the factorization and renormalization scales by factors of 0.5 or 2 with respect to the nominal scale of $(2m_t)^2 + (\sum p_T^{\text{parton}})^2$, where p_T^{parton} are the transverse momenta of the partons in the event. The uncertainties from the parton distribution functions (PDF) and the value of the strong coupling constant α_S were estimated following the procedures from the MSTW2008 [12], CTEQ6.6 [13], and NNPDF2.0 [14] sets. The uncertainties were then combined according to the PDF4LHC prescriptions [15].

The t -channel single top NLO cross section was calculated to be $\sigma_t = 64.6^{+3.4}_{-3.2}$ pb using MCFM [11, 16–18]. The uncertainty was evaluated in the same way as for top-quark pair production. The single top-quark associated production (tW) cross section was set to $\sigma_{tW} = 15.7 \pm 1.2$ pb [19]. The s -channel single top-quark next-to-next-to-leading-log (NNLL) cross section was determined to be $\sigma_s = 4.6 \pm 0.1$ pb [20].

The NNLO cross section of the inclusive production of W bosons multiplied by its branching fraction to leptons was determined to be $\sigma_{W \rightarrow \ell\nu} = 31.3 \pm 1.6$ nb using FEWZ [21], setting the renormalization and factorization scales to $(m_W)^2 + (\sum p_T^{\text{jet}})^2$ with $m_W = 80.398$ GeV/ c^2 . The uncertainty was determined in the same way as in top-quark pair production. The normalizations of the W+b jets and W+c jets components were determined in a measurement of the top pair production cross section in the lepton+jet channel [22], where a simultaneous fit of the $t\bar{t}$ cross section and the normalization of the main backgrounds was performed.

The Drell–Yan production cross section at NNLO was calculated using FEWZ as $\sigma_{Z/\gamma^* \rightarrow \ell\ell}(m_{\ell\ell} > 20 \text{ GeV}) = 5.00 \pm 0.27$ nb, where $m_{\ell\ell}$ is the invariant mass of the two leptons and the scales were set using the Z boson mass $m_Z = 91.1876$ GeV/ c^2 [23].

All generated events were passed through the full simulation of the CMS detector based on GEANT4 [24]. The samples were generated with a different pileup distribution than that observed in the data. The simulated events were therefore reweighted to match the observed pileup distribution.

4 Algorithms for b-jet identification

A variety of reconstructed objects – tracks, vertices and identified leptons – can be used to build observables that discriminate between b and light-parton jets. Several simple and ro-

bust algorithms use just a single observable, while others combine several of these objects to achieve a higher discrimination power. Each of these algorithms yields a single discriminator value for each jet. The minimum thresholds on these discriminators define loose (“L”), medium (“M”), and tight (“T”) operating points with a misidentification probability for light-parton jets of close to 10%, 1%, and 0.1%, respectively, at an average jet p_T of about $80\text{ GeV}/c$. Throughout this paper, the tagging criteria will be labelled with the letter characterizing the operating point appended to the acronym of one of the algorithms described in Sections 4.2 and 4.3. The application of such a tagging criterion will be called a “tagger”.

After a short description of the reconstructed objects used as inputs, details on the tagging algorithms are given in the following subsections, proceeding in order of increasing complexity. Muon-based b-jet identification is mainly used as a reference method for performance measurements. It is described in more detail in Section 5.

4.1 Reconstructed objects used in b-jet identification

Jets are clustered from objects reconstructed by the particle-flow algorithm [25, 26]. This algorithm combines information from all subdetectors to create a consistent set of reconstructed particles for each event. The particles are then clustered into jets using the anti- k_T clustering algorithm [27] with a distance parameter of 0.5. The raw jet energies are corrected to obtain a uniform response in η and an absolute calibration in p_T [28]. Although particle-flow jets are used as the default, the b-jet tagging algorithms can be applied to jets clustered from other reconstructed objects.

Each algorithm described in the next section uses the measured kinematic properties of charged particles, including identified leptons, in a jet. The trajectories of these particles are reconstructed in the CMS tracking system in an iterative procedure using a standard Kalman filter-based method. Details on the pattern recognition, the track-parameter estimation, and the tracking performance in proton-proton collisions can be found in Refs. [4, 29].

A “global” muon reconstruction, using information from multiple detector systems, is achieved by first reconstructing a muon track in the muon chambers. This is then matched to a track measured in the silicon tracker [30]. A refit is then performed using the measurements on both tracks.

Primary vertex candidates are selected by clustering reconstructed tracks based on the z coordinate of their closest approach to the beam line. An adaptive vertex fit [31] is then used to estimate the vertex position using a sample of tracks compatible with originating from the interaction region. Among the primary vertices found in this way, the one with the highest $\sum(p_T^{\text{track}})^2$ is selected as a candidate for the origin of the hard interaction, where the p_T^{track} are the transverse momenta of the tracks associated to the vertex.

The b-jet tagging algorithms require a sample of well-reconstructed tracks of high purity. Specific requirements are imposed in addition to the selection applied in the tracking step. The fraction of misreconstructed or poorly reconstructed tracks is reduced by requiring a transverse momentum of at least $1\text{ GeV}/c$. At least eight hits must be associated with the track. To ensure a good fit, $\chi^2/\text{n.d.o.f.} < 5$ is required, where n.d.o.f. stands for the number of degrees of freedom in the fit. At least two hits are required in the pixel system since track measurements in the innermost layers provide most of the discriminating power. A loose selection on the track impact parameters is used to further increase the fraction of well-reconstructed tracks and to reduce the contamination by decay products of long-lived particles, e.g. neutral kaons. The impact parameters d_{xy} and d_z are defined as the transverse and longitudinal distance to

the primary vertex at the point of closest approach in the transverse plane. Their absolute values must be smaller than 0.2 cm and 17 cm, respectively. Tracks are associated to jets in a cone $\Delta R < 0.5$ around the jet axis, where the jet axis is defined by the primary vertex and the direction of the jet momentum. The distance of a track to the jet axis is defined as the distance of closest approach of the track to the axis. In order to reject tracks from pileup this quantity is required to be less than $700 \mu\text{m}$. The point of closest approach must be within 5 cm of the primary vertex. This sample of associated tracks is the basis for all algorithms that use impact parameters for discrimination.

Properties of the tracks and the average multiplicity after the selection (except for the variable plotted) are shown in Fig. 1. The uncertainties shown in this and all following figures are statistical unless otherwise stated. The data were recorded with a prescaled jet trigger in the second part of 2011 when the number of pileup events was highest. The jet p_{T} threshold was $60 \text{ GeV}/c$. The distributions show satisfactory agreement with the expectations from simulation. The track multiplicity and the lower part of the momentum spectrum are particularly sensitive to the modelling of the particle multiplicity and kinematics by the Monte Carlo generator, as are other distributions such as the number of hits in the innermost pixel layers. Detector effects that are not modelled by the simulation, such as the dynamic readout inefficiency in the pixel system, can also contribute to the remaining discrepancies. In Fig. 1 and the following figures, simulated events with gluon splitting to $b\bar{b}$ are shown as a special category. The b jets in these events tend to be close in space and can be inadvertently merged by the clustering algorithm, resulting in a higher average track multiplicity per jet.

The combinatorial complexity of the reconstruction of the decay points (secondary vertices) of b or c hadrons is more challenging in the presence of multiple proton-proton interactions. In order to minimize this complexity a different track selection is applied. Tracks must be within a cone of $\Delta R = 0.3$ around the jet axis with a maximal distance to this axis of 0.2 cm and pass a “high-purity” criterion [32]. The “high-purity” criterion uses the normalized χ^2 of the track fit, the track length, and impact parameter information to optimize the purity for each of the iterations in track reconstruction. The vertex finding procedure begins with tracks defined by this selection and proceeds iteratively. A vertex candidate is identified by applying an adaptive vertex fit [31], which is robust in the presence of outliers. The fit estimates the vertex position and assigns a weight between 0 and 1 to each track based on its compatibility with the vertex. All tracks with weights > 0.5 are then removed from the sample. The fit procedure is repeated until no new vertex candidate can be found. In the first iteration the interaction region is used as a constraint in order to identify the prompt tracks in the jet. The subsequent iterations produce decay vertex candidates.

4.2 Identification using track impact parameters

The impact parameter of a track with respect to the primary vertex can be used to distinguish the decay products of a b hadron from prompt tracks. The IP is calculated in three dimensions by taking advantage of the excellent resolution of the pixel detector along the z axis. The impact parameter has the same sign as the scalar product of the vector pointing from the primary vertex to the point of closest approach with the jet direction. Tracks originating from the decay of particles travelling along the jet axis will tend to have positive IP values. In contrast, the impact parameters of prompt tracks can have positive or negative IP values. The resolution of the impact parameter depends strongly on the p_{T} and η of a track. The impact parameter significance S_{IP} , defined as the ratio of the IP to its estimated uncertainty, is used as an observable. The distributions of IP values and their significance are shown in Fig. 2. In general, good agreement with simulation is observed with the exception of a small difference in the width of

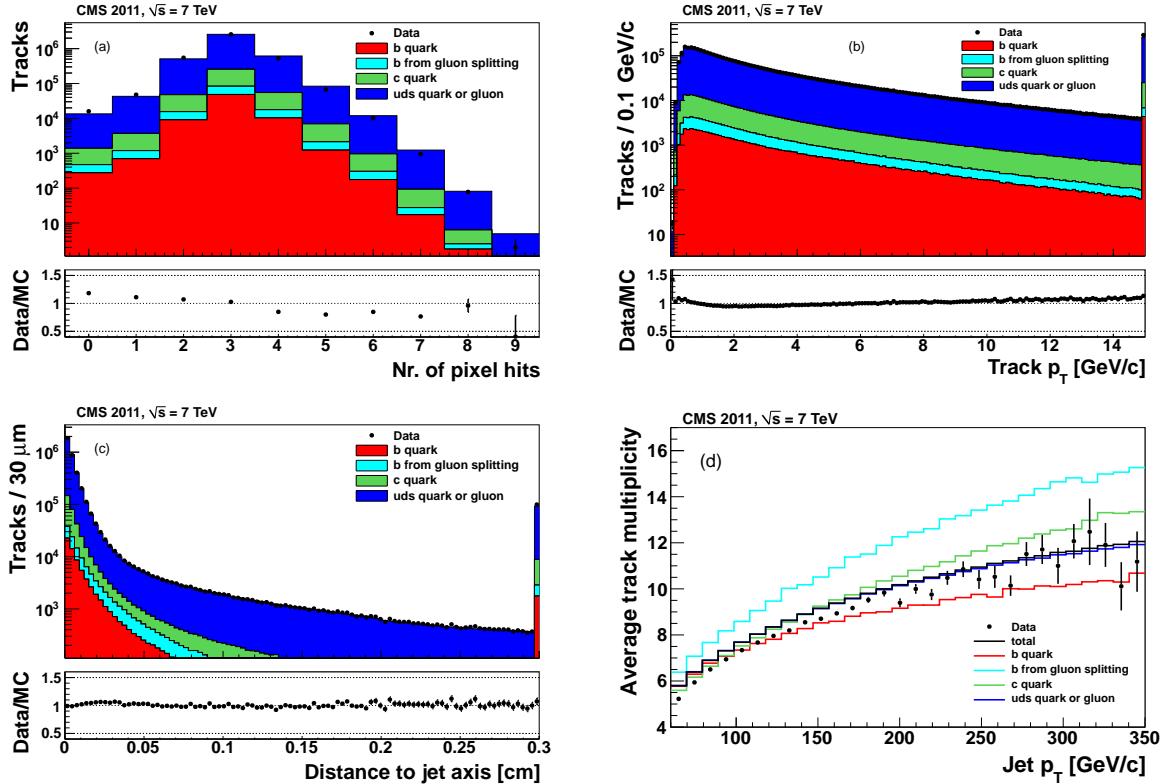

Figure 1: Track properties after basic selection (except for the variable plotted): (a) number of hits in the pixel system, (b) transverse momentum, (c) distance to the jet axis. The average number of tracks passing the basic selection is shown in (d) as a function of the transverse momentum of the jet. In (a)–(c) the distributions from simulation have been normalized to match the counts in data. The filled circles correspond to data. The stacked, coloured histograms indicate the contributions of different components from simulated multijet (“QCD”) samples. Simulated events involving gluon splitting to b quarks (“b from gluon splitting”) are indicated separately from the other b production processes (“b quark”). In each histogram, the rightmost bin includes all events from the overflow. The sample corresponds to a trigger selection with jet $p_T > 60 \text{ GeV}/c$.

the core of the IP significance distribution.

By itself the impact parameter significance has discriminating power between the decay products of b and non-b jets. The *Track Counting* (TC) algorithm sorts tracks in a jet by decreasing values of the IP significance. Although the ranking tends to bias the values for the first track to high positive IP significances, the probability to have several tracks with high positive values is low for light-parton jets. Therefore the two different versions of the algorithm use the IP significance of the second and third ranked track as the discriminator value. These two versions of the algorithm are called *Track Counting High Efficiency* (TCHE) and *Track Counting High Purity* (TCHP), respectively. The distribution of the TCHE discriminator is shown in Fig. 3 (a).

A natural extension of the TC algorithms is the combination of the IP information of several tracks in a jet. Two discriminators are computed from additional algorithms. The *Jet Probability* (JP) algorithm uses an estimate of the likelihood that all tracks associated to the jet come from the primary vertex. The *Jet B Probability* (JBP) algorithm gives more weight to the tracks with the highest IP significance, up to a maximum of four such tracks, which matches the av-

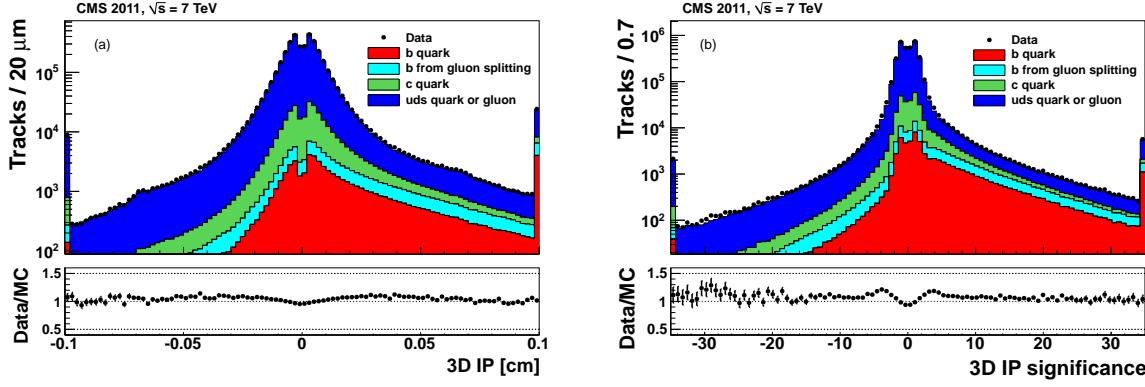

Figure 2: Distributions of (a) the 3D impact parameter and (b) the significance of the 3D impact parameter for all selected tracks. Selection and symbols are the same as in Fig. 1. Underflow and overflow are added to the first and last bins, respectively.

verage number of reconstructed charged particles from b-hadron decays. The estimate for the likelihood, P_{jet} , is defined as

$$P_{\text{jet}} = \Pi \cdot \sum_{i=0}^{N-1} \frac{(-\ln \Pi)^i}{i!} \quad \text{with} \quad \Pi = \prod_{i=1}^N \max(P_i, 0.005), \quad (1)$$

where N is the number of tracks under consideration and P_i is the estimated probability for track i to come from the primary vertex [33, 34]. The P_i are based on the probability density functions for the IP significance of prompt tracks. These functions are extracted from data for different track quality classes, using the shape of the negative part of the S_{IP} distribution. The cut-off parameter for P_i at 0.5% limits the effect of single, poorly reconstructed tracks on the global estimate. The discriminators for the jet probability algorithms have been constructed to be proportional to $-\ln P_{\text{jet}}$. The distribution of the JP discriminator in data and simulation is shown in Fig. 3 (b).

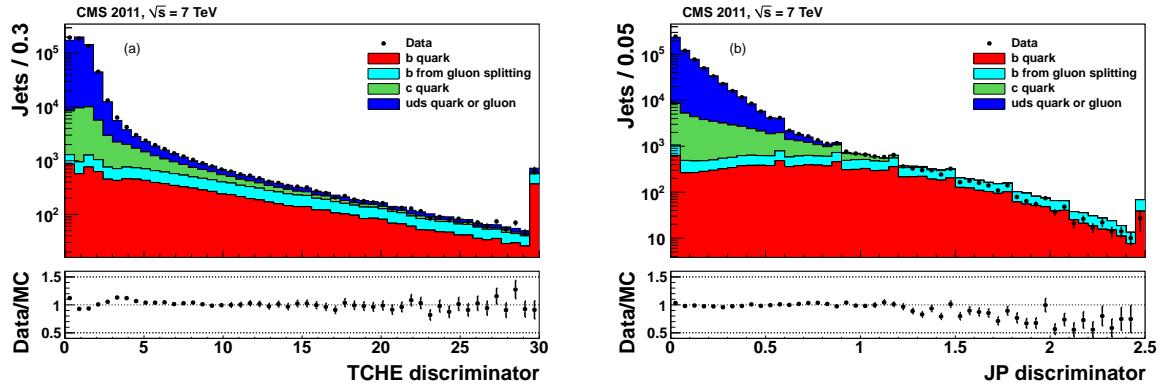

Figure 3: Discriminator values for (a) the TCHE and (b) the JP algorithms. Selection and symbols are the same as in Fig. 1. The small discontinuities in the JP distributions are due to the single track probabilities which are required to be greater than 0.5%.

4.3 Identification using secondary vertices

The presence of a secondary vertex and the kinematic variables associated with this vertex can be used to discriminate between b and non-b jets. Two of these variables are the flight distance and direction, using the vector between primary and secondary vertices. The other

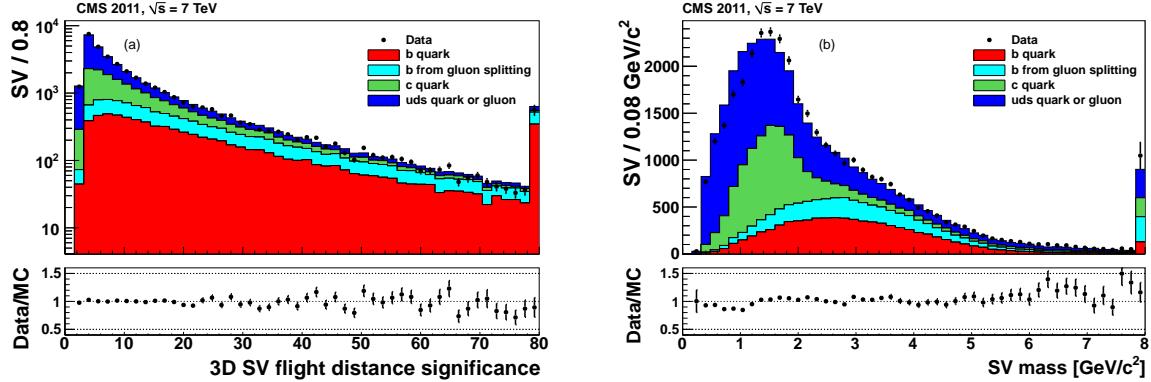

Figure 4: Properties of reconstructed decay vertices: (a) the significance of the 3D secondary vertex (3D SV) flight distance and (b) the mass associated with the secondary vertex. Selection and symbols are the same as in Fig. 1.

variables are related to various properties of the system of associated secondary tracks such as the multiplicity, the mass (assuming the pion mass for all secondary tracks), or the energy. Secondary-vertex candidates must meet the following requirements to enhance the b purity:

- secondary vertices must share less than 65% of their associated tracks with the primary vertex and the significance of the radial distance between the two vertices has to exceed 3σ ;
- secondary vertex candidates with a radial distance of more than 2.5 cm with respect to the primary vertex, with masses compatible with the mass of K^0 or exceeding $6.5 \text{ GeV}/c^2$ are rejected, reducing the contamination by vertices corresponding to the interactions of particles with the detector material and by decays of long-lived mesons;
- the flight direction of each candidate has to be within a cone of $\Delta R < 0.5$ around the jet direction.

The *Simple Secondary Vertex* (SSV) algorithms use the significance of the flight distance (the ratio of the flight distance to its estimated uncertainty) as the discriminating variable. The algorithms' efficiencies are limited by the secondary vertex reconstruction efficiency to about 65%. Similar to the *Track Counting* algorithms, there exist two versions optimized for different purity: the *High Efficiency* (SSVHE) version uses vertices with at least two associated tracks, while for the *High Purity* (SSVHP) version at least three tracks are required. In Fig. 4 the flight distance significance and the mass associated with the secondary vertex are shown.

A more complex approach involves the use of secondary vertices, together with track-based lifetime information. By using these additional variables, the *Combined Secondary Vertex* (CSV) algorithm provides discrimination also in cases when no secondary vertices are found, increasing the maximum efficiency with respect to the SSV algorithms. In many cases, tracks with an $S_{IP} > 2$ can be combined in a “pseudo vertex”, allowing for the computation of a subset of secondary-vertex-based quantities even without an actual vertex fit. When even this is not possible, a “no vertex” category reverts to track-based variables that are combined in a way similar to that of the JP algorithm.

The following set of variables with high discriminating power and low correlations is used (in the “no vertex” category only the last two variables are available):

- the vertex category (real, “pseudo,” or “no vertex”);

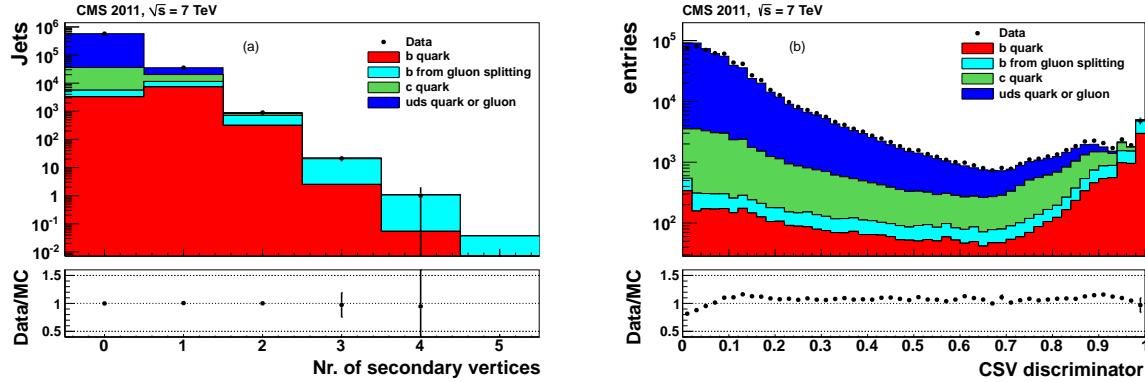

Figure 5: Distributions of (a) the secondary vertex multiplicity and (b) the CSV discriminator. Selection and symbols are the same as in Fig. 1.

- the flight distance significance in the transverse plane (“2D”);
- the vertex mass;
- the number of tracks at the vertex;
- the ratio of the energy carried by tracks at the vertex with respect to all tracks in the jet;
- the pseudorapidities of the tracks at the vertex with respect to the jet axis;
- the 2D IP significance of the first track that raises the invariant mass above the charm threshold of $1.5 \text{ GeV}/c^2$ (tracks are ordered by decreasing IP significance and the mass of the system is recalculated after adding each track);
- the number of tracks in the jet;
- the 3D IP significances for each track in the jet.

Two likelihood ratios are built from these variables. They are used to discriminate between b and c jets and between b and light-parton jets. They are combined with prior weights of 0.25 and 0.75, respectively. The distributions of the vertex multiplicity and of the CSV discriminator are presented in Fig. 5.

4.4 Performance of the algorithms in simulation

The performance of the algorithms described above is summarized in Fig. 6 where the predictions of the simulation for the misidentification probabilities (the efficiencies to tag non-b jets) are shown as a function of the b-jet efficiencies. For loose selections with 10% misidentification probability for light-parton jets a b-jet tagging efficiency of $\sim 80\text{--}85\%$ is achieved. In this region the JBP has the highest b-jet tagging efficiency. For tight selections with misidentification probabilities of 0.1%, the typical b-jet tagging efficiency values are $\sim 45\text{--}55\%$. For medium and tight selections the CSV algorithm shows the best performance. As can be seen in Fig. 6, the TC and SSV algorithms cannot be tuned to provide good performance for the whole range of operating points. Therefore two versions of these algorithms are provided, with the “high efficiency” version to be used for loose to medium operating points and the “high purity” version for tighter selections. Because of the non-negligible lifetime of c hadrons the separation of c from b jets is naturally more challenging. Due to the explicit tuning of the CSV algorithm for light-parton- and c-jet rejection it provides the best c-jet rejection values in the high-purity region.

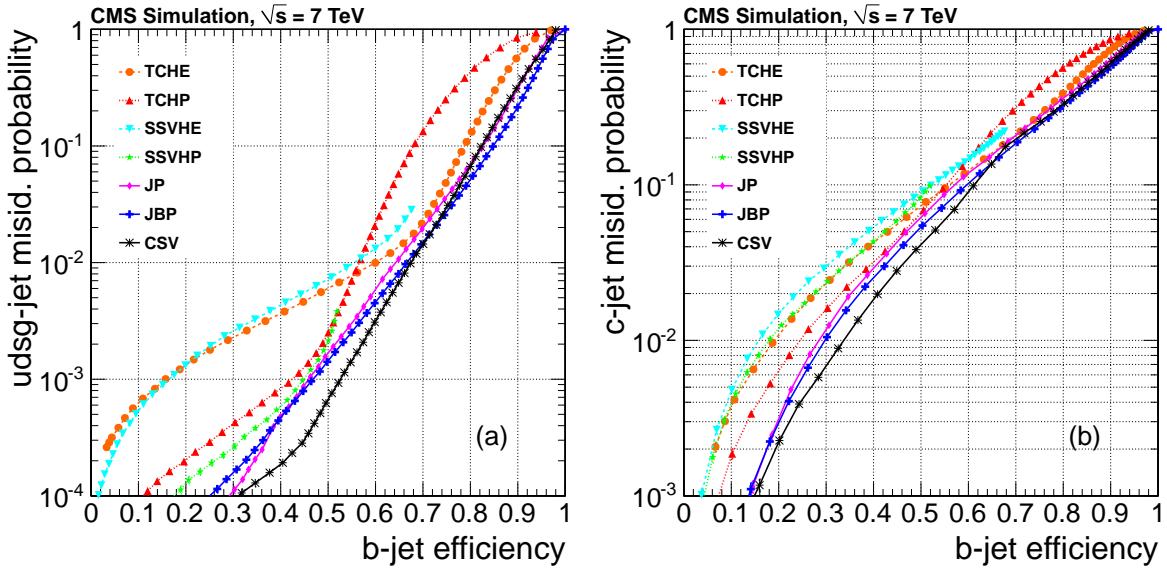

Figure 6: Performance curves obtained from simulation for the algorithms described in the text. (a) light-parton- and (b) c-jet misidentification probabilities as a function of the b-jet efficiency.

4.5 Impact of running conditions on b-jet identification

All tagging algorithms rely on a high track identification efficiency and a reliable estimation of the track parameters and their uncertainties. These are both potentially sensitive to changes in the running conditions of the experiment. The robustness of the algorithms with respect to the misalignment of the tracking system and an increase in the density of tracks due to pile up, which are the most important of the changes in conditions, has been studied.

The alignment of the CMS tracker is performed using a mixture of tracks from cosmic rays and minimum bias collisions [35, 36], and is regularly monitored. During the 2011 data taking, the most significant movements were between the two halves of the pixel barrel detector, where discrete changes in the relative z position of up to $30\ \mu\text{m}$ were observed. The sensitivity of b-jet identification to misalignment was studied on simulated $t\bar{t}$ samples. With the current estimated accuracy of the positions of the active elements, no significant deterioration is observed with respect to a perfectly aligned detector. The effect of displacements between the two parts of the pixel barrel detector was studied by introducing artificial separations of 40, 80, 120, and $160\ \mu\text{m}$ in the detector simulation. The movements observed in 2011 were not found to cause any significant degradation of the performance.

Because of the luminosity profile of the 2011 data, the number of proton collisions taking place simultaneously in one bunch crossing was of the order of 5 to 20 depending on the time period. Although these additional collisions increase the total number of tracks in the event, the track selection is able to reject tracks from nearby primary vertices. The multiplicity distribution of selected tracks is almost independent of the number of primary vertices, as shown in Fig. 7 (a). There is an indication of a slightly lower tracking efficiency in events with high pileup. The rejection of the additional tracks is mainly due to the requirement on the distance of the tracks with respect to the jet axis. This selection criterion is very efficient for the rejection of tracks from pileup. The reconstruction of track parameters is hardly affected. The distribution of the second-highest IP significance is stable, as shown in Fig. 7 (b). The impact of high pileup on the b-jet tagging performance is illustrated in Fig. 8. This shows the light-parton misidentification probability versus the b-jet tagging efficiency for the TCHP and SSVHP algorithms. In order

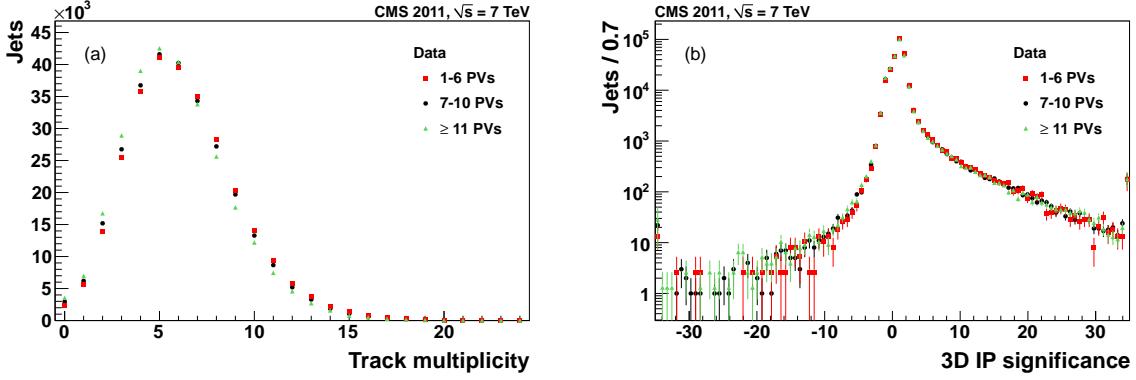

Figure 7: (a) the number of tracks associated with the selected jets for three ranges of primary vertex (PV) multiplicity. (b) the IP significance of the second-most significant track, for the three ranges of primary vertex multiplicity. The distributions are normalized to the event count for 1–6 PV range. Underflow and overflow entries are added to the first and last bins, respectively.

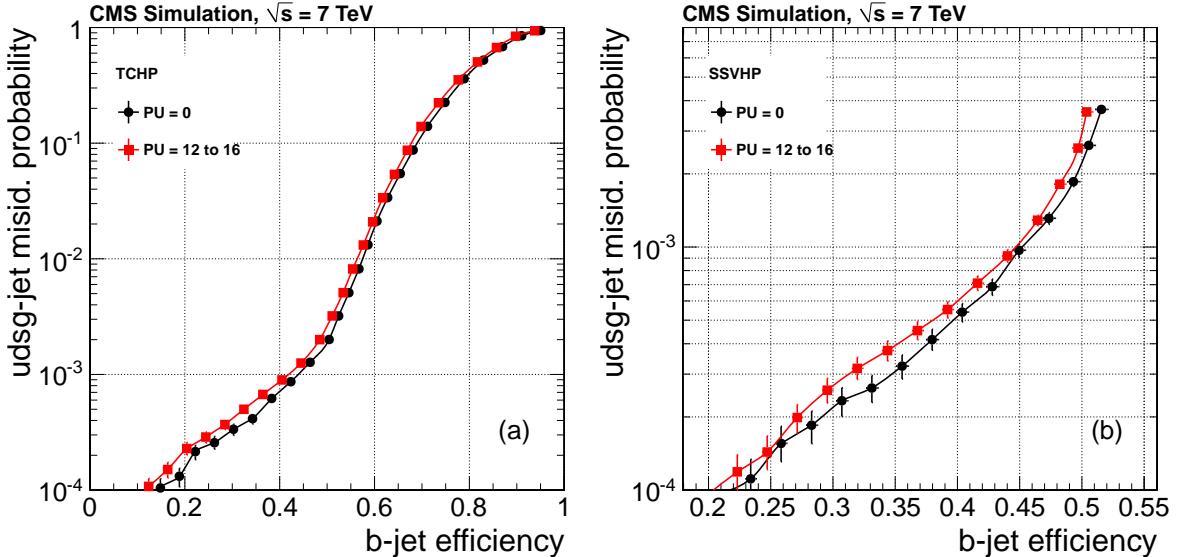

Figure 8: Light-parton misidentification probability versus b-jet tagging efficiency for the (a) TCHP and (b) SSVHP algorithms for different pileup (PU) scenarios.

to focus on the changes due to the b-jet tagging algorithms, the performance curves have been compared using a jet p_T threshold of 60 GeV/c at the generator level. The changes are small and concentrated in the regions of very high purity.

5 Efficiency measurement with multijet events

For the b-jet tagging algorithms to be used in physics analyses, it is crucial to know the efficiency for each algorithm to select genuine b jets. There are a number of techniques that can be applied to CMS data to measure the efficiencies *in situ*, and thus reduce the reliance on simulations. If event distributions from MC simulation match those observed in data reasonably well, then the simulation can be used for a wide range of topologies after applying corrections determined from specific data samples. Corrections can be applied to simulated events using a scale factor SF_b , defined as the ratio of the efficiency measured with collision data to the efficiency

found in the equivalent simulated samples, using MC generator-level information to identify the jet flavour. Furthermore, the measurement techniques used for data are also applied to the simulation in order to validate the different algorithms.

Some efficiency measurements are performed using samples that include a jet with a muon within $\Delta R = 0.4$ from the jet axis (a “muon jet”). Because the semileptonic branching fraction of b hadrons is significantly larger than that for other hadrons (about 11%, or 20% when $b \rightarrow c \rightarrow \ell$ cascade decays are included), these jets are more likely to arise from b quarks than from another flavour. Muons are identified very efficiently in the CMS detector, making it straightforward to collect samples of jets with at least one muon. These muons can be used to measure the performance of the lifetime-based tagging algorithms, since the efficiencies of the muon- and lifetime-based b-jet identification techniques are largely uncorrelated. Sections 5.1 and 5.2 describe efficiency measurements that use muon jets, while the technique of Section 5.3 makes use of a more generic dijet sample. The results are given in Section 7.

5.1 Efficiency measurement with kinematic properties of muon jets

Due to the large b-quark mass, the momentum component of the muon transverse to the jet axis, p_T^{rel} , is larger for muons from b-hadron decays than for muons in light-parton jets or from charm hadrons. This component is used as the discriminant for the “PtRel” method. In addition, the impact parameter of the muon track, calculated in three dimensions, is also larger for b hadrons than for other hadrons. This parameter is used as the discriminant for the “IP3D” method. Both of these variables can thus be used as a discriminant in the b-jet tagging efficiency determination. In both cases, the discriminating power of the variable depends on the muon jet p_T . The muon p_T^{rel} (IP) distributions provide better separation for jets with p_T smaller (greater) than about 120 GeV/ c . The PtRel and IP3D methods rely on fits to the p_T^{rel} [37] and muon IP distributions in the data with respect to simulated spectra for the b signal and charm+light-parton background.

In the two methods, the p_T^{rel} and IP spectra for muon jets are modelled using simulated distributions that represent the spectra expected for different jet flavours to obtain the b-jet content of the sample. The efficiency for a particular tagger is obtained by measuring the fraction of muon jets that satisfy the requirements of the tagger. To make the treatment of the statistical uncertainty more straightforward, the muon jet sample is separated into those jets that satisfy and those that fail the requirements of the tagger. These jets are referred to as “tagged” and “untagged.”

A dijet sample with high b-jet purity is obtained by requiring that events have exactly two reconstructed jets: the muon jet as defined above and another jet fulfilling the TCHPM b-jet tagging criterion (the “medium” operating point for the TCHP algorithm). Simulated MC events are used to establish p_T^{rel} and IP spectra for muon jets resulting from the fragmentation of b, c, and light partons. Muons in light-parton jets mostly arise from the decay of charged pions or kaons and from misidentified muons or hadronic punch-through in the calorimeters, effects that might not be modelled well in the simulation. The spectra for light-parton jets from simulation can be validated against control samples of collision data. In Fig. 9 the distributions of p_T^{rel} and $\ln(|\text{IP}|[\text{cm}])$ derived from the simulation are compared to the ones obtained for tracks in inclusive jet data by applying the same kinematic selection and track reconstruction quality requirements as for the muon candidates. In order to measure the ability of the simulation to model the investigated spectra, we apply the same procedure to a sample of simulated inclusive jet events. The spectra derived for low- p_T muons from light-parton jets in simulation are corrected by multiplying them with the ratio of shapes of the inclusive distributions obtained

in data and simulation on a bin-by-bin basis.

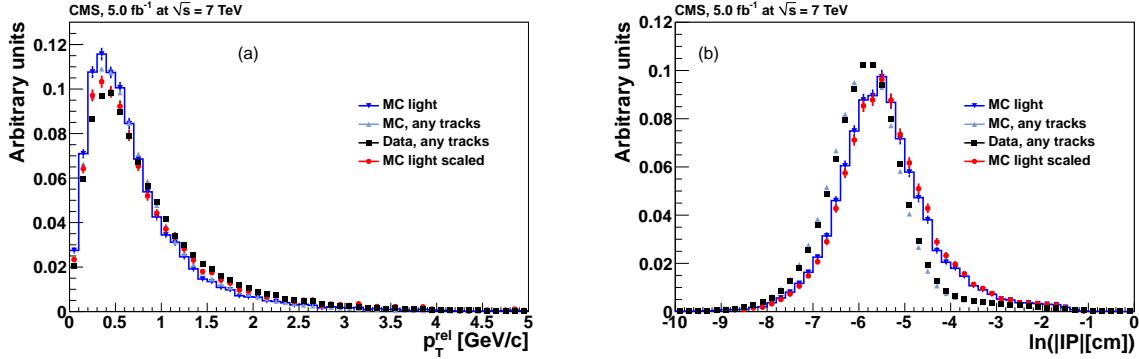

Figure 9: Comparison of distributions of (a) muon p_T^{rel} for jets with p_T between 80 and 120 GeV/ c and (b) $\ln(|\text{IP}|/\text{cm})$ for jets with p_T between 160 and 320 GeV/ c for muons in simulated light-parton jets (“MC light”), tracks from simulated inclusive jet events (“any tracks”), tracks from data, and muons in simulated light-parton jets after corrections based on data (“MC light scaled”).

The fractions of each jet flavour in the dijet sample are extracted with a binned maximum likelihood fit using p_T^{rel} and IP templates for b, c and light-parton jets derived from simulation or inclusive jet data. The fits are performed independently in the tagged and untagged subsamples of the muon jets. Results of representative fits are shown in Figs. 10 and 11.

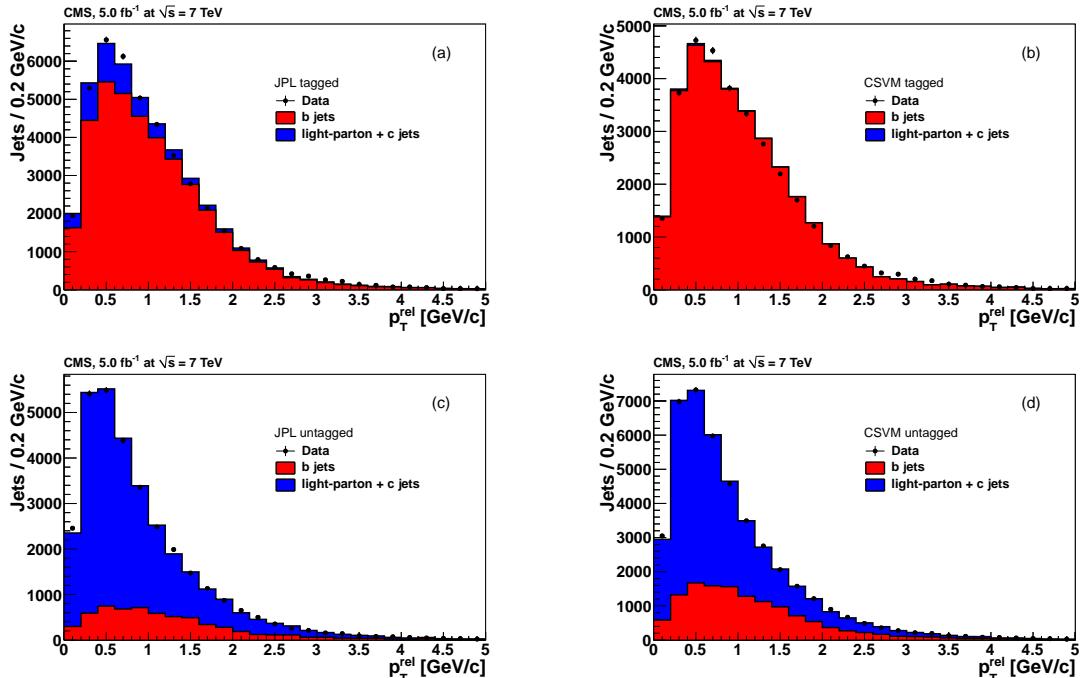

Figure 10: Fits of the summed b and non-b templates, for simulated muon jets, to the muon p_T^{rel} distributions from data. (a) and (c) show the results for muon jets that pass (tagged) or fail (untagged) the b-jet tagging criteria of the JPL method. (b) and (d) are the equivalent plots for the CSV method. The muon jet p_T is between 80 and 120 GeV/ c .

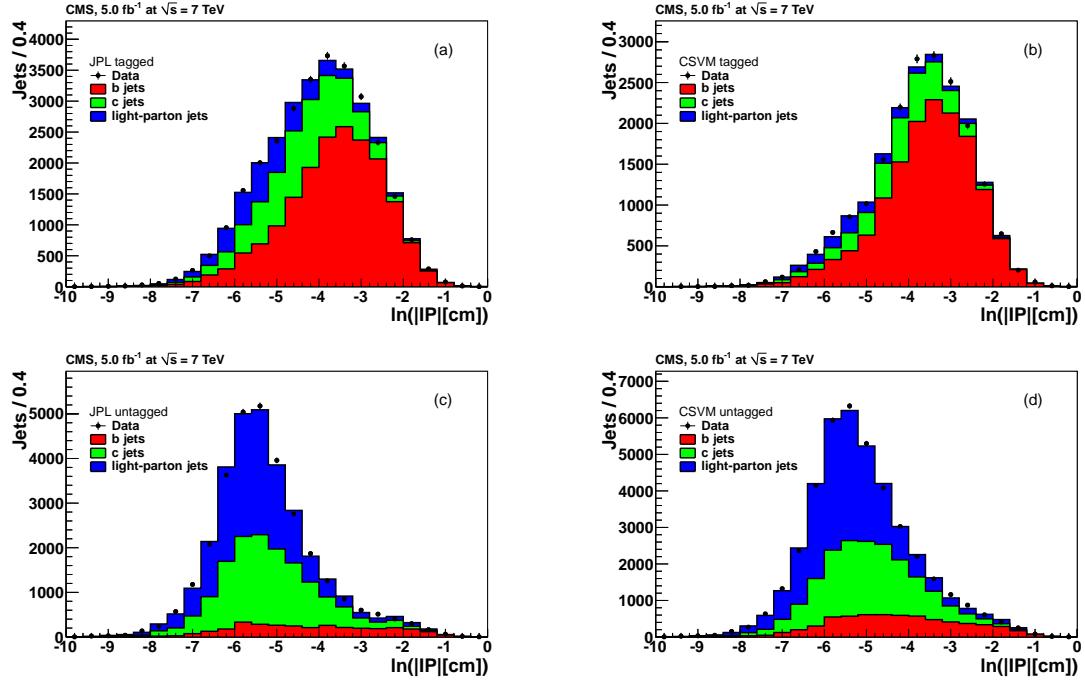

Figure 11: Same as Fig. 10 using the $\ln(|\text{IP}| [\text{cm}])$ distributions. The muon jet p_{T} is between 160 and 320 GeV/c .

From each fit the fractions of b jets ($f_b^{\text{tag}}, f_b^{\text{untag}}$) are extracted from the data. With these fractions and the total yields of tagged and untagged muon jets ($N_{\text{data}}^{\text{tag}}, N_{\text{data}}^{\text{untag}}$), the number of b jets in these samples are calculated, and the efficiency $\varepsilon_b^{\text{tag}}$ for tagging b jets in the data is inferred:

$$\varepsilon_b^{\text{tag}} = \frac{f_b^{\text{tag}} \cdot N_{\text{data}}^{\text{tag}}}{f_b^{\text{tag}} \cdot N_{\text{data}}^{\text{tag}} + f_b^{\text{untag}} \cdot N_{\text{data}}^{\text{untag}}} . \quad (2)$$

To obtain SF_b , the efficiency for tagging b jets in the simulation is obtained from jets that have been identified as b jets with MC generator-level matching.

5.2 Efficiency measurement with the System8 method

The “System8” method [38, 39] is applied to events with a muon jet and at least one other, “away-tag”, jet. The muon jet is used as a probe. The reference lifetime tagger and a supplementary $p_{\text{T}}^{\text{rel}}$ -based selection are tested on this jet. The away-tag jet is tested with a separate lifetime tagger. There are eight quantities that can be counted from the full data sample. The quantities depend on the number of passing or failing tags. A set of equations correlates these eight quantities with the tagging efficiencies.

A muon jet can be tagged as a b jet using either a lifetime tagger, or by requiring that the muon has large $p_{\text{T}}^{\text{rel}}$. In this analysis, the requirement is $p_{\text{T}}^{\text{rel}} > 0.8 \text{ GeV}/c$. These two tagging criteria have efficiencies $\varepsilon_b^{\text{tag}}$ and $\varepsilon_b^{\text{PtRel}}$, respectively, for b jets. The third tagging criterion is the requirement that another jet in the event passes also a lifetime-based tagger. This last requirement defines the “away-tag sample”. It enriches the b content of the events, and thus makes it more likely that the muon jet is a b jet. Correlations between the efficiencies of the two tagging criteria are estimated from simulation. As $p_{\text{T}}^{\text{rel}}$ provides less discrimination between jet flavours at higher jet energies, the System8 method loses sensitivity for jet $p_{\text{T}} > 120 \text{ GeV}/c$.

With these criteria eight quantities are measured. The four quantities for the muon jets are: the total number of muon jets in the sample n , the number of muon jets that pass the lifetime-tagging criterion n^{tag} , the number of muon jets that pass the p_T^{rel} requirement n^{PtRel} , and the number of muon jets that pass both criteria $n^{\text{tag,PtRel}}$. Likewise, the four quantities for the away-tag sample are labelled p , p^{tag} , p^{PtRel} , $p^{\text{tag,PtRel}}$. The away-tag jets are tagged with the TCHPL criterion.

The full muon jet sample, n , and the away-tag sample, p , are each composed of an unknown mix of b and non-b jets. The non-b jets are labelled “ $c\ell$ ”. The muon sample thus comprises n_b and $n_{c\ell}$, and the away-tag sample, p_b and $p_{c\ell}$. The efficiencies of the two tagging criteria on b jets ($\varepsilon_b^{\text{tag}}$, $\varepsilon_b^{\text{PtRel}}$) and on non-b jets ($\varepsilon_{c\ell}^{\text{tag}}$, $\varepsilon_{c\ell}^{\text{PtRel}}$) are also unknown, for a total of eight unknown quantities. Thus, a system of eight equations can be written that relates the measurable quantities to the unknowns:

$$\begin{aligned} n &= n_b + n_{c\ell}, \\ p &= p_b + p_{c\ell}, \\ n^{\text{tag}} &= \varepsilon_b^{\text{tag}} n_b + \varepsilon_{c\ell}^{\text{tag}} n_{c\ell}, \\ p^{\text{tag}} &= \beta^{\text{tag}} \varepsilon_b^{\text{tag}} p_b + \alpha^{\text{tag}} \varepsilon_{c\ell}^{\text{tag}} p_{c\ell}, \\ n^{\text{PtRel}} &= \varepsilon_b^{\text{PtRel}} n_b + \varepsilon_{c\ell}^{\text{PtRel}} n_{c\ell}, \\ p^{\text{PtRel}} &= \beta^{\text{PtRel}} \varepsilon_b^{\text{PtRel}} p_b + \alpha^{\text{PtRel}} \varepsilon_{c\ell}^{\text{PtRel}} p_{c\ell}, \\ n^{\text{tag,PtRel}} &= \beta^n \varepsilon_b^{\text{tag}} \varepsilon_b^{\text{PtRel}} n_b + \alpha^n \varepsilon_{c\ell}^{\text{tag}} \varepsilon_{c\ell}^{\text{PtRel}} n_{c\ell}, \\ p^{\text{tag,PtRel}} &= \beta^p \varepsilon_b^{\text{tag}} \varepsilon_b^{\text{PtRel}} p_b + \alpha^p \varepsilon_{c\ell}^{\text{tag}} \varepsilon_{c\ell}^{\text{PtRel}} p_{c\ell}. \end{aligned} \quad (3)$$

The method assumes that the efficiencies for a combination of tagging criteria are factorizable. Thus eight correlation factors are introduced to solve the system of equations: α^{tag} , β^{tag} , α^{PtRel} , β^{PtRel} , α^n , β^n , α^p , and β^p . These factors are obtained from the simulation as a function of the muon jet p_T and $|\eta|$. The factors α and β are determined for non-b and b jets, respectively. The superscripts “tag” and “PtRel” of α and β indicate the efficiency ratio of the p to the n samples for the lifetime and p_T^{rel} criteria. The superscripts “ n ” and “ p ” refer to the correlation between the two tagging efficiencies, “tag” and “PtRel”, in the n and p samples.

The simulation predicts that the correlation coefficients typically range between 0.95 and 1.05 for those associated with the b-jet tagging efficiencies, and between 0.7 and 1.2 for those associated with the $c+\ell$ -tagging efficiencies. A numerical computation is applied to solve the system of eight equations in the data to determine the eight unknowns, thus simultaneously determining the tagging efficiencies and flavour contents of both the full and away-tag samples.

5.3 Efficiency measurement using a reference lifetime algorithm

While muon p_T^{rel} provides less discrimination power between jet flavours at large jet p_T , the lifetime-based algorithms described in Sections 4.2 and 4.3 (TCHE, TCHP, JP, JBP, SSVHE, SSVHP and CSV) retain their sensitivity to distinguish different jet flavours. In particular, the discriminant for the jet probability algorithm has different distributions for different jet flavours for jet momenta in the range $30 < p_T < 700 \text{ GeV}/c$. The JP algorithm can be calibrated directly with data. Tracks with negative impact parameter are used to compute the probability that those tracks come from the primary vertex. The same calibration is performed separately in simulated samples. As a result, the JP algorithm serves as a reference for estimating the fraction of b jets in a data sample, and also for estimating the fraction of b jets in a subsample that has been selected by an independent tagging algorithm. In this manner the efficiency of the

independent algorithm can be measured. This method is called the lifetime tagging method (“LT”). It can be performed on both inclusive and muon jet samples. The resulting scale factors are compared to obtain an estimate of the systematic uncertainty.

The efficiency measurement is performed in inclusive jet events in which at least one jet must be above a given p_T threshold, and separately in dijet events in which at least one jet is a muon jet. To increase the fraction of b jets in the inclusive sample, an additional jet tagged by the JPM algorithm is also required. The sample with muon jets is already sufficiently enriched in b jets by the muon requirement. The same set of samples can be established with simulated events, so that the true tagging efficiency can be measured there and a scale factor computed.

Because a value of the JP discriminant can be defined for jets that have as few as one track with a positive impact parameter significance, the discriminant can be calculated for most b jets, regardless of their p_T . The fraction of b jets that have JP information, C_b , rises from about 0.91 at $p_T = 20 \text{ GeV}/c$ to more than 0.98 for $p_T > 50 \text{ GeV}/c$.

Figure 12 shows the JP discriminant distributions in the muon jet sample and the inclusive sample, before and after tagging the jets with an independent tagger, in this case the CSVM tagger. Also shown is a fit to the distributions using JP-discriminant templates derived from simulations of b, c, and light-parton jets. The normalization of the relative flavour fractions f_b , f_c and f_{light} is left free, with the constraint that $f_b + f_c + f_{\text{light}} = 1$. The b-jet tagging efficiency is the ratio of the number of b jets that are tagged by the independent tagger to the number of b jets before the tagging. The numbers are calculated using the fit. The b-jet tagging efficiency is corrected for the fraction of jets that have JP information.

$$\varepsilon_b^{\text{tag}} = \frac{C_b \cdot f_b^{\text{tag}} \cdot N_{\text{data}}^{\text{tag}}}{f_b^{\text{before tag}} \cdot N_{\text{data}}^{\text{before tag}}}, \quad (4)$$

where the superscripts “before tag” and “tag” refer to the samples before and after application of the tagging criterion.

Examples of the efficiencies measured for the JPL and CSVM taggers are shown in Fig. 13. In both cases the results from simulation are close to those obtained from data.

This technique cannot be used to measure the efficiency of the JP algorithm itself, as the JP discriminant is used in the fit to determine the b-jet content of the sample. However, the CSV discriminant, which is mostly based on information from secondary vertices, can be used in its place to determine the flavour content. More than 90% of jets have CSV information, as is the case with the JP discriminant. But unlike the JP discriminant, the CSV discriminant cannot be calibrated solely with the data. To remedy this, the CSV discriminant is used to estimate the tagging efficiency of the TC algorithms. By comparing these results to those using the JP discriminant, the bias due to using the CSV discriminant is determined to be (0–2%, 4–6%, 6–9%) for the (loose, medium, tight) operating points. The efficiencies and scale factors for the JP algorithm are corrected for these biases.

5.4 Systematic uncertainties on efficiency measurements

Several systematic uncertainties affect the measurement of the b-jet tagging efficiency. Some are common to all four methods (PtRel, IP3D, System8, LT), some are common to a subset of them, and some are unique to a particular method.

Common systematic uncertainties for all methods:

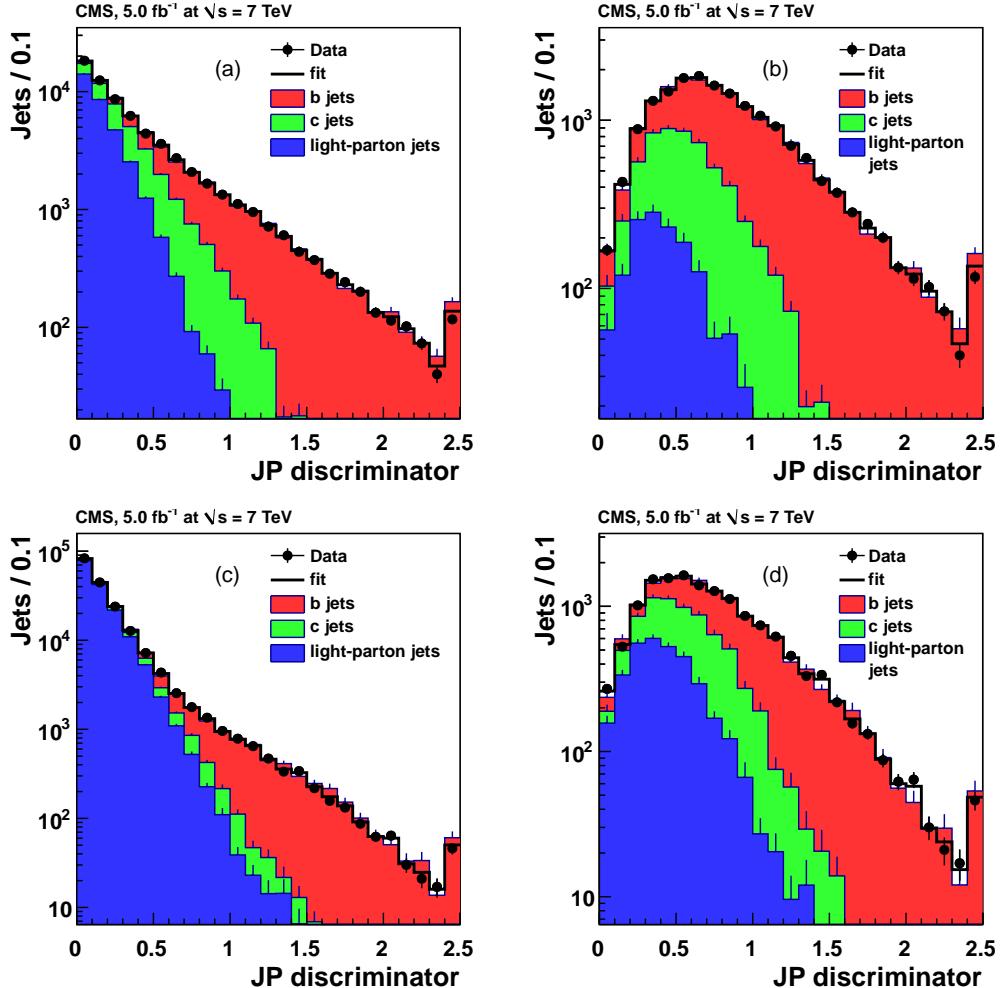

Figure 12: Fits of the summed b, c and light-parton templates, for simulated jets, to the JP-discriminant distributions from data. (a) and (c) show the results for muon jets before and after identification with the CSV tagger, respectively. (b) and (d), the equivalent plots for inclusive jets. The jet p_T is in the range $260 < p_T < 320 \text{ GeV}/c$. Overflows are displayed in the rightmost bins.

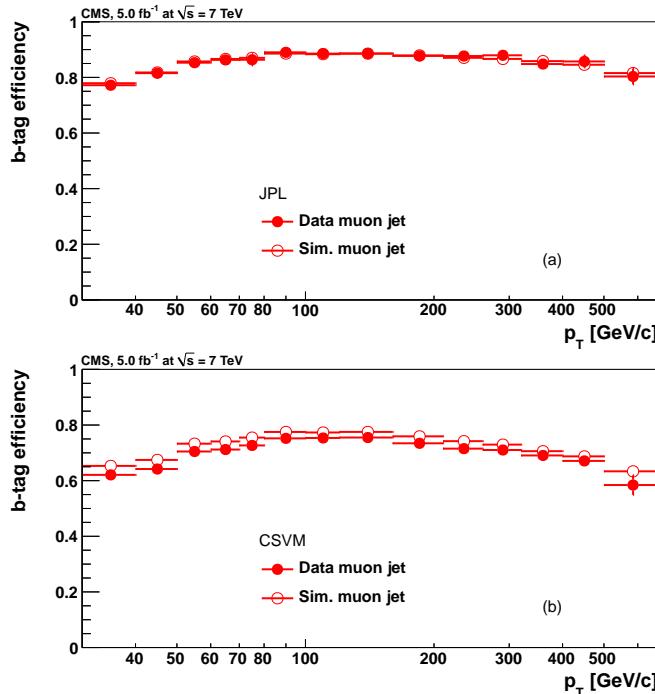

Figure 13: Efficiencies for the identification of b-jets measured for (a) the JPL and (b) the CSV tagger with the LT method in the muon jet sample. Filled and open circles correspond to data and simulation, respectively.

- **Pileup:** The measured b-jet tagging efficiency depends on the number of pp collisions superimposed on the primary interaction of interest. The systematic uncertainty is computed by varying the average value of the pileup in data by 10% and calculating the difference in the values of SF_b after reweighting the simulation with the modified distribution.
- **Gluon splitting:** Studies of angular correlation between b jets at the LHC [40] indicate that QCD events may have a larger fraction of gluon splitting into $b\bar{b}$ pairs than is assumed in the generation of the simulation. A study was carried out with the MC sample where the number of events with gluon splitting was artificially changed by 50%. Results obtained with this modified gluon splitting MC sample are then compared to those with the original sample. The observed deviation is quoted as a systematic uncertainty.
- **Muon p_T^μ :** The central value of the b-jet tagging efficiency is extracted from data with muon $p_T^\mu > 5$ GeV/c. The choice of the selection affects the shape of the template distributions used in fits, and also the number of events used to measure the tagging efficiencies. The p_T^μ threshold is varied up to 9 GeV/c to test the sensitivity to this choice.

Common uncertainty for the PtRel, IP3D and System8 methods:

- **Away-jet tagger:** The dependency of the calculated b-jet tagging efficiency on the away-jet tagger is studied by comparing the results obtained by tagging the away jets with different variants of the TC algorithm (TCHEL, TCHEM, TCHPM). The measured SF_b tends to increase when the away tag is tighter. The maximum deviation from the default away-jet tagger is taken as a systematic uncertainty.

Uncertainty unique to the PtRel method:

- **Ratio of light-parton to charm jets in simulation:** The shapes of the p_T^{rel} and IP spectra for light-parton jets have been obtained from control samples in data, which minimizes the bias due to a mismodelling of the muon kinematics in the simulation. However, since the p_T^{rel} distribution in data is fitted with a sum of templates for b jets and for c+udsg jets, uncertainties on the ratio between light-parton and charmed jets in the simulation must be considered. To do so, the predicted ratio is varied by $\pm 20\%$, and the fit is repeated, taking the variation in the results as a systematic uncertainty. This uncertainty does not apply to the IP method, where a three-component fit is performed that determines the light-parton and charm contributions independently.

Uncertainties unique to the System8 method:

- **Selection on p_T^{rel} :** One of the System8 criteria is a selection on the muon $p_T^{\text{rel}} > 0.8 \text{ GeV}/c$. In order to test the sensitivity to the b purity in the muon jet sample and the relative charm/light-parton fraction in the non-b background, this selection was changed from 0.5 to $1.2 \text{ GeV}/c$ in the data. The correlation factors were recomputed accordingly in the simulation and the System8 method was applied again to the data in order to compute the b-jet tagging efficiency. The largest deviation observed from the central value is quoted as a systematic uncertainty.
- **MC closure test:** The b-jet tagging efficiency can be directly calculated from the simulated QCD muon-enriched sample, as the flavour of the jets at generator level is known. In this case, the efficiency can be measured by taking the number of identified true b jets over all true b jets. The resulting value is denoted as the MC truth b-jet tagging efficiency. The System8 method is also applied to this MC sample. The resulting b-jet tagging efficiencies are in good agreement with the MC truth, giving a negligible systematic uncertainty. (This systematic uncertainty does not appear for the other methods as they rely on template fits, making such a test trivial.)

Uncertainties unique to the LT method:

- **Fraction of b jets with JP information:** The fraction of inclusive jets with JP information is well described by the simulation. As explained above, the number of b jets before tagging is measured by a fit to the JP distribution and corrected by the fraction C_b of b jets with JP information. A systematic uncertainty of half the residual correction, $(1 - C_b)/(2C_b)$, is estimated from the simulation as a function of the b-jet p_T . A corresponding factor with a similar uncertainty is needed for measuring the efficiency of the JP and JBP taggers with the CSV discriminator spectrum.
- **Difference between muon jets and inclusive jets:** The difference between the measured SF_b in muon jets and in inclusive b jets is taken as a systematic uncertainty. This is the largest contribution to the systematic uncertainty on SF_b with the LT method. Due to the large statistical uncertainty on SF_b for inclusive jets with $p_T < 80 \text{ GeV}/c$, the same systematic uncertainty is used for $p_T < 80 \text{ GeV}/c$ and for the range $80\text{--}210 \text{ GeV}/c$. If the difference on SF_b between muon jets and inclusive jets is smaller than the statistical error on SF_b for inclusive jets, this uncertainty is used for the systematic uncertainty estimate.
- **Bias for the JP and JBP taggers:** The uncertainty on the measurement of the bias, when using the CSV discriminant to measure the efficiency of the JP and JBP taggers as estimated for the TC taggers, is propagated into the uncertainty on the scale

factors for these taggers.

The systematic uncertainties on the data/MC scale factors for different tagging criteria are detailed in Tables 1–4 for the PtRel and System8 methods at low jet p_T ($80 < p_T < 120 \text{ GeV}/c$) and for the IP3D and LT methods at higher jet p_T ($160 < p_T < 320 \text{ GeV}/c$). In these momentum ranges the average uncertainty is about 3% for the PtRel method, 6–10% for the System8 method, 3–4% for the IP3D method, and 2–7% for the LT method.

Table 1: Relative systematic uncertainties on SF_b for the PtRel method in the muon jet p_T range 80–120 GeV/c , using the medium operating point of the b-jet tagging algorithms.

6 Efficiency measurement with $t\bar{t}$ events

In the framework of the standard model, the top quark is expected to decay to a W boson and a b quark about 99.8% of the time [23]. Experimentally, the measurement of the heavy-flavour content of $t\bar{t}$ events can provide either a direct measurement of the branching fraction of the decay of the top quark to a W boson and a b quark, $B(t \rightarrow Wb)$, or, assuming $B(t \rightarrow Wb) = 1$,

Table 4: Relative systematic uncertainty on SF_b with the LT method in the muon jet p_T range 160–320 GeV/ c , using the medium operating point of the b-jet tagging algorithms.

b tagger	pileup	$g \rightarrow b\bar{b}$	p_T^μ	C_b	inc. jets	bias	total
JPM	0.1%	0.8%	0.5%	0.1%	4.4%	4.0%	6.0%
JBPM	0.1%	0.4%	0.8%	0.1%	4.3%	4.0%	5.9%
TCHEM	0.1%	1.6%	0.3%	0.2%	2.8%	—	3.2%
TCHPM	0.2%	0.5%	0.5%	0.2%	1.7%	—	1.9%
SSVHEM	0.1%	2.3%	0.8%	0.2%	6.6%	—	7.0%
CSVM	0.2%	2.3%	0.7%	0.2%	5.2%	—	5.7%

the b-jet tagging efficiency. The b jets in $t\bar{t}$ events have an average p_T of about 80 GeV/ c and cover a p_T range relevant for many processes both within the standard model and for many models beyond the standard model.

In this Section, we present several methods to study the heavy-flavour content of $t\bar{t}$ events. The profile likelihood ratio (PLR) method, described in Section 6.3, and the flavour tag matching (FTM) method, described in Section 6.5, use $t\bar{t}$ events in the dilepton channel in which both W bosons decay into leptons. The flavour tag consistency (FTC) method, described in Section 6.4, and the bSample method (Section 6.6) use $t\bar{t}$ events in the lepton+jets channel, in which one W boson decays into quarks and the other into a charged lepton and a neutrino. These methods are used to measure the efficiency of tagging b jets to be measured in the data and the simulation over the average p_T and η range of jets in the top-quark events. The differences in efficiencies observed between the data and MC simulation are provided as a data/MC scale factor SF_b similar to the techniques described in Section 5.

6.1 Event selection

The event reconstruction used herein follows closely the event selection performed for the $t\bar{t}$ production cross section measurements [22, 41], with the exception of the b-jet tagging requirements. All objects are reconstructed using a particle-flow algorithm.

In the lepton+jets channel, the final state is composed of four jets, one energetic isolated muon and missing transverse energy. Events are required to pass a single-muon trigger. After offline reconstruction, events are selected requiring exactly one isolated muon with $p_T > 30$ GeV/ c and $|\eta| < 2.1$ and at least four jets with $p_T > 30$ GeV/ c and $|\eta| < 2.4$. The FTC method further requires that the two leading jets have transverse momenta greater than 70 GeV/ c and 50 GeV/ c respectively, and that the transverse momentum of the muon is greater than 35 GeV/ c . The reconstructed missing transverse energy (\cancel{E}_T) is required to be above 20 GeV.

In the dilepton channel, the final state is composed of two jets, two energetic isolated leptons (electron or muon) and missing transverse energy. Events are required to pass dilepton triggers in which two muons, two electrons, or one electron and one muon are required to be present. After offline reconstruction, events are selected with two isolated, oppositely charged leptons with $p_T > 20$ GeV/ c and $|\eta| < 2.5$ (2.4) for electrons (muons), at least two jets with $p_T > 30$ GeV/ c and $|\eta| < 2.4$, and $\cancel{E}_T > 30$ GeV for ee/ $\mu\mu$ events. The selected leptons and jets are required to originate from the same primary interaction vertex. Events with same-flavour lepton pairs in the dilepton mass window ($76 < m_{\ell\ell} < 106$ GeV/ c^2) are removed to suppress the dominant Z+jet background. Dilepton pairs from heavy-flavour resonances and low-mass Drell-Yan production are also removed by requiring a minimum dilepton invariant mass of 12 GeV/ c^2 .

Table 5: Number of observed and predicted events in the lepton+jets sample after applying all selection requirements of the FTC method. All MC samples have been scaled to an integrated luminosity of 2.3 fb^{-1} . The uncertainties include the uncertainties on the luminosity and the cross sections. The CSVM operating point has been used for the b-jet tagging requirement.

	no tagging	≥ 1 b-tagged jets	≥ 2 b-tagged jets
$t\bar{t}$	8504 ± 1275	7425 ± 1113	3744 ± 561
Single top	477 ± 82	394 ± 118	162 ± 49
W+jets	6170 ± 1851	1367 ± 410	214 ± 64
Z+jets	459 ± 138	83 ± 25	15 ± 5
QCD	23 ± 7	3 ± 1	0.20 ± 0.06
Total prediction	15633 ± 2253	9272 ± 1921	4134 ± 566
Data	14391	8781	3897

The numbers of observed and predicted events in the lepton+jets channel and the dilepton channel are given in Tables 5 and 6, respectively. The uncertainties include the uncertainties on the luminosity measurement and the cross sections. For all MC predictions, events are reweighted to take into account differences in trigger and lepton selection efficiencies between data and simulation [22, 41]. The lepton selection efficiency scale factors are estimated from data using Z events. For dilepton events, the trigger efficiencies are estimated on a data sample using a trigger that is weakly correlated to the dilepton triggers. The dilepton trigger selection efficiency is estimated on events which contain two leptons that fulfil the complete dilepton event selection.

The Drell–Yan background is measured using data. Two different methods are used, and the two estimates are compatible. In the PLR method, for the ee and $\mu\mu$ channels, the ratio of Drell–Yan events outside and inside the dilepton invariant mass window, $R_{\text{out/in}}$, is estimated from the simulation. This is used to estimate the Drell–Yan background using the number of data events inside the dilepton invariant mass window [41]. A contamination from other backgrounds can still be present in the Z-mass window, and this contribution is subtracted using the $e\mu$ channel scaled according to the event yields in the ee and $\mu\mu$ channels. For the $e\mu$ channel, the DY background yield is estimated after performing a binned maximum-likelihood fit to the dilepton invariant mass distribution. In the FTM method, the number of Drell–Yan events ee and $\mu\mu$ channels is estimated from the shape of the distribution of the angle between the momentum of the two leptons. For the $e\mu$ channel, the predictions are taken from simulation.

6.2 Systematic uncertainties

Most of the sources of systematic uncertainties are common to all methods, and several methods have specific additional contributions. A description of the common systematic uncertainties is given in this section. The description of the procedure to estimate the systematic uncertainties in each analysis and the influence of the different sources will be given separately for each analysis in its relevant section.

There are different sources of uncertainties originating from detector knowledge or related to the theory and the simulation. These uncertainties can affect the normalization factor for each process or they can distort the distributions themselves.

The dominant sources of uncertainty arise from the MC simulation. The uncertainty due to the modelling of the underlying event is estimated by comparing results between the main sample generated with the Z2 tune to that with the D6T tune [42]. The effect due to the scale used to match clustered jets to partons (i.e., jet-parton matching) is estimated with dedicated samples

Table 6: Number of observed and predicted events in the dilepton sample after applying all selection requirements of the PLR method. All MC samples have been scaled to a luminosity of 2.3 fb^{-1} . The uncertainties include the uncertainties on the luminosity and the cross sections. The TCHEL operating point has been used for the b-jet tagging requirement. The component “ $t\bar{t}$ signal” stands for the dilepton events. The component “ $t\bar{t}$ other” contains the events in all other decay channels.

Processes	Channel ee	Channel $\mu\mu$	Channel e μ
Without b-jet tagging requirement			
$t\bar{t}$ signal	971 ± 147	1275 ± 182	3453 ± 521
$t\bar{t}$ other	11.5 ± 5.7	3.3 ± 1.7	23.6 ± 11.8
Single top	48.7 ± 14.6	62.7 ± 18.9	163.7 ± 49.0
Di-bosons	22.3 ± 6.7	29.2 ± 8.8	49.4 ± 14.8
Z+jets	409 ± 204	545 ± 273	200 ± 100
W+jets	12.0 ± 6.0	< 0.5	11.4 ± 5.7
Total prediction	1475 ± 259	1915 ± 343	3902 ± 512
Data	1442	1773	3898
With ≥ 1 b-tagged jets			
Total prediction	1088 ± 170	1429 ± 218	3390 ± 475
Data	1080	1364	3375
With ≥ 2 b-tagged jets			
Total prediction	529 ± 73	697 ± 97	1827 ± 263
Data	554	686	1854

generated by varying the nominal matching p_T thresholds by factors of 2 and 1/2. Effects due to the definition of the renormalization and factorization scales used in the simulation of the signal are studied with dedicated MC samples with the scales varied simultaneously by factors of 2 and 1/2. The uncertainties related to the parton distribution function (PDF) used to model the hard scattering of the proton-proton collisions are estimated by varying the parameters of the PDF by $\pm 1\sigma$ with respect to their nominal values and using the PDF4LHC prescription [13, 15]. Variations in the relative composition of the simulated samples are studied by varying the contributions of each background with respect to the signal and each other.

Several systematic uncertainties pertain to the modelling of the CMS detector in the MC simulations. Important uncertainties are the energy scales of the jets and, to a lesser extent, of the leptons, as they shift the momenta of the reconstructed objects. Similarly, the uncertainty in jet energy resolution has also been considered. The effects of the jet energy scale are taken into account by varying the energy scale of the jets according to its uncertainty [28]. A further source comes from the uncertainties associated with the measurement of the trigger and lepton selection efficiencies. The uncertainty due to pileup is evaluated by varying the mean value of the measured pileup distribution by $\pm 10\%$.

6.3 Profile likelihood ratio method

In this method, the data/MC scale factor of the b-jet tagging efficiency is measured with the PLR method using the 2-dimensional distribution of the jet multiplicity versus the b-tagged jet multiplicity in dilepton events. The uncertainties in the event yield and in the shape of the distribution are considered as nuisance parameters in the likelihood function and are then fitted during the minimization procedure. This leads to combined statistical and systematic uncertainties associated with the measurement of the scale factor.

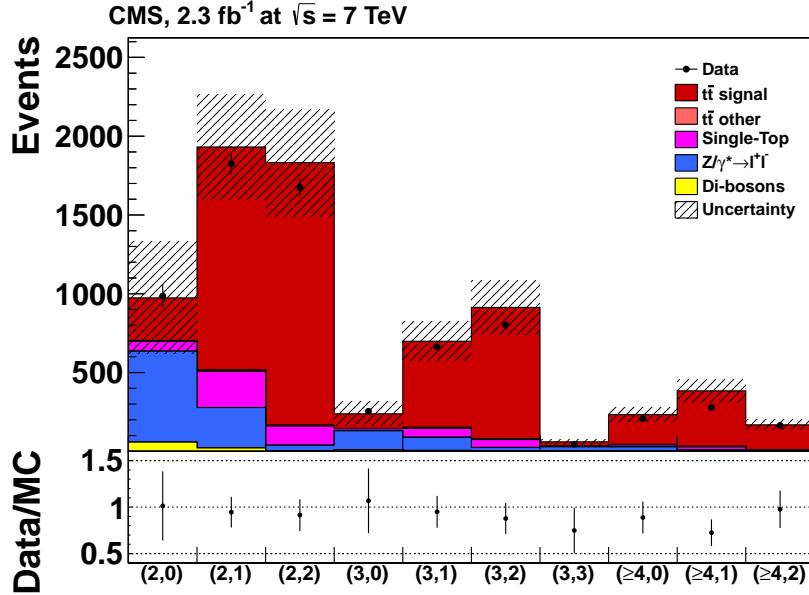

Figure 14: Number of b-tagged jets per event in the dilepton channel for the TCHEL operating point, in the data (filled circles) and the simulation (solid histograms), before the fit. The simulated distribution is normalized to an integrated luminosity of 2.3 fb^{-1} . The bin labels (m, n) refer to the number of events with m jets in the event of which n are tagged. The component “ $t\bar{t}$ signal” are the dilepton events, and the component “ $t\bar{t}$ other” contains the events in all other decay channels. The hatched area corresponds to the combined statistical and systematic uncertainty.

The likelihood function for a given dilepton channel j (ee , $e\mu$ or $\mu\mu$) and a given bin i of the 2-dimensional distribution (corresponding to n jets and m b-tagged jets) is written as [43]:

$$\mathcal{L}_{i,j}(SF_b, N_{i,j}^{\text{obs}}, \{U_k\}) = \text{Poisson}(N_{i,j}^{\text{obs}}, \mu_{i,j}(SF_b, \{U_k\})) \times \prod_k \text{Gauss}(U_k, 0, 1), \quad (5)$$

where $N_{i,j}^{\text{obs}}$ is the number of observed events, $\mu_{i,j}$ the number of expected events, and U_k the nuisance parameters. The distribution of the number of b-tagged jets observed in data and predicted in the simulation for the TCHEL operating point for $t\bar{t}$ and background events is shown in Fig. 14. The likelihood function for a given channel j is then the product of the likelihood functions over all the bins of the distribution:

$$\mathcal{L}_j(SF_b, \{N_{i,j}^{\text{obs}}\}, \{U_k\}) = \prod_i \mathcal{L}_{i,j}(SF_b, N_{i,j}^{\text{obs}}, \{U_k\}). \quad (6)$$

Since the decay channels are statistically independent, the overall likelihood function is then simply the product of the individual channel likelihoods:

$$\mathcal{L}(SF_b, \{N_{i,j}^{\text{obs}}\}, \{U_k\}) = \prod_j \mathcal{L}_j. \quad (7)$$

The expression of the profile likelihood ratio LR is then

$$LR(SF_b) = \frac{\mathcal{L}(SF_b, \{\hat{U}_i\})}{\mathcal{L}(\hat{SF}_b, \{\hat{U}_i\})}, \quad (8)$$

where \hat{U}_i represents the conditional maximum likelihood estimates of U_i obtained with the scale factor SF_b fixed while $S\hat{F}_b$ and \hat{U}_i are the estimates obtained with SF_b free.

The distribution of $-2 \ln(LR(SF_b))$ is asymptotically distributed as a χ^2 distribution with one degree of freedom (Wilk's theorem [44]). An LR curve is obtained by scanning the values of SF_b in a given range and used to determine a 68% confidence level interval. These uncertainties are the combination of the statistical uncertainty and the systematic uncertainties considered as nuisance parameters. All the nuisance parameters are common to the three channels except the estimation of the backgrounds from data for $W+jets$ and $Z+jets$. The $Z+jets$ background is estimated from data as described in Section 6.1. The small $W+jets$ background is estimated from data using the matrix method [41].

The expected number of b-tagged jets in events with n jets of a given dilepton final state, $\mu_{i,j}$ in Eq.(5), is derived from pre-tagged simulated events with n jets. This is carried out by applying per-jet b-jet tagging efficiencies, considering all jet tagging combinations. These efficiencies are derived as a function of p_T and η , using simulated $t\bar{t}$ events for b jets and using data samples dominated by light-parton jets. A constant scale factor SF_b is applied to the b- and c-jet efficiencies to model the b-jet tagging efficiency in data. The value of SF_b is then extracted by minimizing the LR as described above. A closure test is performed on simulated signal events to check that, for a unit scale factor, the b-tagged jet multiplicity distribution obtained with the reweighting procedure is the same as the one obtained directly from MC simulation using a requirement on the b-jet tagging discriminant.

Several uncertainties are considered as nuisance parameters in the likelihood function and are then fitted during the minimization procedure. These are the uncertainties on the energy scale of the jets and the leptons, the expected number of events of the different contributions, and the uncertainty on the light-parton jet scale factor.

Further contributions to the systematic uncertainties are estimated outside the PLR procedure. The expected input distributions to the PLR method are re-derived, using MC samples with varied parameters, and the b-jet tagging scale factors are re-measured. The relative differences of SF_b with respect to the nominal values are taken as systematic uncertainties, and added in quadrature to the total uncertainty from the fit. These uncertainties include the uncertainties on the jet-parton matching scale, the parton-shower/matrix-element threshold, and the top mass.

The factorization scale is the dominant systematic uncertainty, as it affects the jet multiplicity distribution, with a relative uncertainty of approximately 1.7% on the scale factor of the CSVL operating point. The second-largest contribution is from the uncertainty on the $t\bar{t}$ event yield, which is estimated to be 20%. It includes the uncertainties on the $t\bar{t}$ cross section, the trigger and lepton selection efficiencies, and the branching fraction of the decays of the W bosons. This results in an uncertainty of 1.4% on the scale factor of the CSVL operating point. Further, the statistical uncertainty on the b-jet tagging efficiency in the simulation was found to range between 0.4% and 1.6% depending on the operating point considered. A 1.6% systematic uncertainty on the scale factor was therefore chosen for all the operating points.

Finally, to account for a possible uncertainty coming from the fitting algorithm itself, an additional uncertainty is estimated using different choices of the likelihood minimization. This is taken as a 1% relative uncertainty.

6.4 Flavour tag consistency method

The FTC method requires consistency between the observed and expected number of tags in the lepton+jets events to study the performance of the heavy-flavour algorithms.

In a sample of $t\bar{t}$ pair candidates in the lepton+jets channel, the expected number of events with n b-tagged jets $\langle N_n \rangle$ can be written as

$$\langle N_n \rangle = L \cdot \sigma_{t\bar{t}} \cdot \varepsilon \cdot \sum_{i,j,k} F_{ijk} \sum_{i'+j'+k'=n}^{i' \leq i, j' \leq j, k' \leq k} [C_i^{i'} \varepsilon_b^{i'} (1 - \varepsilon_b)^{(i-i')} C_j^{j'} \varepsilon_c^{j'} (1 - \varepsilon_c)^{(j-j')} C_k^{k'} \varepsilon_l^{k'} (1 - \varepsilon_l)^{(k-k')}], \quad (9)$$

where L is the integrated luminosity, $\sigma_{t\bar{t}}$ is the $t\bar{t}$ cross section, ε is the pre-tagging selection efficiency, C_a^b is the binomial coefficient, and $\varepsilon_b, \varepsilon_c$, and ε_l are the b-, c-, and light-parton jet tagging efficiencies. The factors F_{ijk} are the fractions of events with i b jets, j c jets, and k light-parton jets. They are derived from the $t\bar{t}$ simulation in which the true flavour of the jets is known.

As an example, the F_{112} term contributes to the expected number of events with 1 b-tagged jet $\langle N_1 \rangle$ in the following way:

$$\langle N_1 \rangle \propto F_{112} \times \left(\underbrace{1 \cdot \varepsilon_b (1 - \varepsilon_c) (1 - \varepsilon_l)^2}_{\text{the b jet}} + \underbrace{1 \cdot (1 - \varepsilon_b) \varepsilon_c (1 - \varepsilon_l)^2}_{\text{the c jet}} + \underbrace{2 \cdot (1 - \varepsilon_b) (1 - \varepsilon_c) \varepsilon_l (1 - \varepsilon_l)}_{\text{the light-parton jet}} \right). \quad (10)$$

To account for the non-negligible amount of background, Eq. (9) is modified to include each background sample:

$$\begin{aligned} \langle N_n \rangle &= \langle N_n^{t\bar{t}} \rangle + \langle N_n^{\text{background}} \rangle \\ &= L \cdot \sigma_{t\bar{t}} \cdot \varepsilon_{t\bar{t}} \cdot \left[\sum_{i,j,k} F_{ijk}^{t\bar{t}} \sum_{i'+j'+k'=n}^{i' \leq i, j' \leq j, k' \leq k} (\dots) \right. \\ &\quad \left. + \frac{\sigma_{\text{background}}}{\sigma_{t\bar{t}}} \cdot \frac{\varepsilon_{\text{background}}}{\varepsilon_{t\bar{t}}} \cdot \sum_{i,j,k} F_{ijk}^{\text{background}} \sum_{i'+j'+k'=n}^{i' \leq i, j' \leq j, k' \leq k} (\dots) \right], \end{aligned} \quad (11)$$

where (\dots) stands for the expression in square brackets from Eq. (9).

The tagging efficiencies and the $t\bar{t}$ production cross section are then measured by minimizing the log-likelihood function:

$$\mathcal{L} = -2 \log \prod_n \mathcal{Poisson}(N_n, \langle N_n \rangle), \quad (12)$$

where N_n is the number of observed events with n b-tagged jets. The distribution of the number of b-tagged jets observed in data and predicted in the simulation before and after the fit for $t\bar{t}$ and background events is shown in Fig. 15.

In the current implementation the likelihood only uses the b-tagged jet multiplicity in $t\bar{t}$ lepton+jets events with between four to seven reconstructed jets, as it emphasizes the measurement of the heavy-flavour b-jet tagging efficiency. The b-jet tagging efficiencies and $t\bar{t}$ cross section are treated as free parameters in the fit. The $t\bar{t}$ cross section determined in the fits are consistent with the published values. The c- and light-parton-jet tagging efficiencies are taken from the simulation corrected for the data/MC scale factors.

The systematic uncertainties are determined from ensembles of pseudo-experiments. In each of these pseudo-experiments, the number of signal and background events are generated using Poisson statistics, using as mean values the number of expected events in each channel. Events

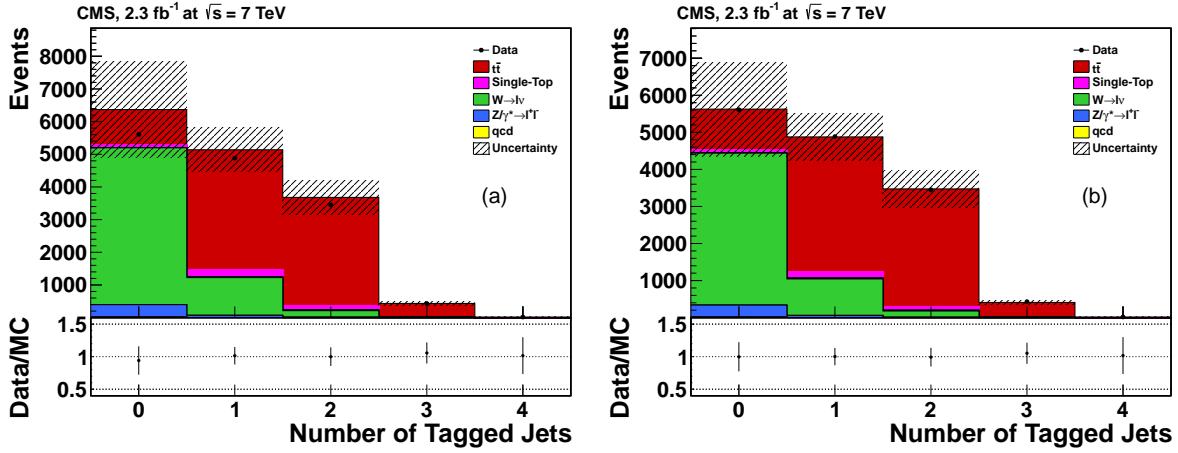

Figure 15: Number of tagged jets per event in the lepton+jet channel with the FTC method with the CSVM operating point, in the data (filled circles) and the simulation (solid histograms), (a) before and (b) after the fit. The simulated distribution is normalized to an integrated luminosity of 2.3 fb^{-1} . The hatched area corresponds to the combined statistical and systematic uncertainty.

are then randomly chosen in the simulated samples and the b-tagged jet multiplicity distributions are populated according to the simulated jet multiplicity in each event. The measurement is then performed as described above using the factors F_{ijk} from the nominal simulation. The average b-jet tagging efficiency is compared to the average b-jet tagging efficiency value measured in ensemble tests with the nominal samples. The difference is taken as a systematic uncertainty.

The dominant contribution is the uncertainty on the jet energy scale, with a relative uncertainty of 2.2% on the scale factor of the CSVM operating point. The second-largest uncertainty arises from the uncertainty on the production cross section of the W+heavy flavour jets, with a relative uncertainty of 0.97%. The uncertainties due to the factorization scale and the jet-parton matching are 0.41% and 0.35%, respectively, for the CSVM operating point.

6.5 Flavour tag matching method

The FTM method requires consistency between the observed and expected number of tags in dilepton events. The expected number of events with n b-tagged jets $\langle N_n \rangle$ is written as

$$\langle N_n \rangle = \sum_{\substack{\text{all jets} \\ k \text{ jets}=2}} n_k \cdot P_{n,k}, \quad (13)$$

where n_k is the observed number of events with k jets, and $P_{n,k}$ is the probability to count n b-tagged jets in a k -jet event. These probability functions are written in terms of the tagging efficiencies and the expected jet composition.

In order to illustrate explicitly the construction of the probability functions, the exclusive two-jet multiplicity bin is used and the following expression is obtained:

$$P_{n,2} = \sum_{\substack{i \text{ jets}=0 \\ \text{from top decay}}}^2 \alpha_i \cdot P_{n,2,i}, \quad (14)$$

where $P_{n,2,i}$ is the probability that n b tags are observed in an event with two jets of which i jets come from $t\bar{t}$ decays.

The misassignment probabilities α_i denote the probability in the sample that i jets from the decay of the $t\bar{t}$ pair have been reconstructed and selected. These are normalized such that $\sum_i \alpha_i = 1$. For example, α_2 is the probability that both b jets from the $t\bar{t}$ decay have been selected. They take into account both the contribution from the background, which is small in the dilepton channel, and jet misassignment. Either or both of the jets from the decays of the two top quarks may not be selected, and jets from initial- and final- state radiation, or jets from the proton recoil may enter the selection, further diluting the sample.

As an example, for the case where two tagged jets are found in a two-jet event, the probabilities can be explicitly written as:

$$\begin{aligned} P_{2,2,0} &= \varepsilon_q^2 && \text{if no jets are from } t\bar{t} \text{ decays;} \\ P_{2,2,1} &= 2\varepsilon_b \varepsilon_q && \text{if 1 jet is from } t\bar{t} \text{ decays;} \\ P_{2,2,2} &= \varepsilon_b^2 && \text{if 2 jets are from } t\bar{t} \text{ decays.} \end{aligned} \quad (15)$$

The misidentification probability ε_q is an effective measurement of the probability of tagging gluon, light and charm quark jets in the dilepton sample. Similar expressions can easily be derived for the other jet multiplicity bins.

The misassignment probabilities are determined from data, and used in the subsequent likelihood of the b-tagged jet multiplicity distribution. In order to estimate the actual fraction of b jets from top-quark decays in the selected sample, kinematic properties of the top decay topology are used. The invariant mass of the lepton-jet pairs from a $t \rightarrow Wb$ decay have a kinematic end-point at $M_{\ell,b}^{\max} \equiv \sqrt{m_t^2 - m_W^2} \approx 156 \text{ GeV}/c^2$. The invariant mass of misassigned lepton-jet pairs exhibits a longer tail towards high mass values. The shape of the misassigned pairs can be modelled by mixing lepton-jet pairs from different events or randomly changing the lepton momentum direction. The fraction of jets from $t \rightarrow Wb$ decays can thus be measured normalizing the spectrum obtained from the combinatorial model to the number of pairs observed in the tail (i.e. $M_{\ell,b} > 180 \text{ GeV}/c^2$). This is estimated independently for each dilepton channel and for each jet-multiplicity bin. The procedure is checked and found to be unbiased from MC pseudo-experiments. Taking into account the expected contribution of $t\bar{t}$ and single-top events to the final sample, the sample composition in terms of events with 2, 1, or 0 correctly reconstructed and selected b jets is estimated.

The b-jet tagging efficiency ε_b can then be measured by maximizing the likelihood function:

$$\mathcal{L}(\varepsilon_b, \varepsilon_q, \alpha_i) = \prod_{n=0}^{\text{all jets}} \text{Poisson}(N_n, \langle N_n \rangle), \quad (16)$$

where N_n is the observed number of events with n b-tagged jets.

The likelihood only uses the b tagged jet multiplicity in $t\bar{t}$ dilepton events with two and three reconstructed jets. Gaussian constraints are added for the effective c- and light-parton jet tagging efficiency ε_q and the misassignment probabilities:

$$\mathcal{L} = \prod_{n=0}^{\text{all jets}} \text{Poisson}(N_n, \langle N_n \rangle) \cdot \prod_i \text{Gauss}(\alpha_i, \hat{\alpha}_i, \sigma_{\alpha_i}) \cdot \text{Gauss}(\varepsilon_q, \hat{\varepsilon}_q, \sigma_{\varepsilon_q}). \quad (17)$$

The central value $\hat{\varepsilon}_q$ and width σ_{ε_q} of ε_q are determined from the simulation. For the misassignment probabilities α_i , the central values $\hat{\alpha}_i$ are taken from the measurement described above,

and the width σ_{α_i} derived from the uncertainty of the expected contribution of $t\bar{t}$ and single-top events to the final sample.

The systematic uncertainties affect the measurement of the b-jet tagging probability through their effect on the parameters of the fit, namely the measured misassignment probabilities and the misidentification probability for non-b jets. The effect on the measured misassignment probabilities is determined from ensembles of pseudo-experiments, where, for each source of uncertainty, the bias on the probabilities is determined. Most sources of uncertainties such as jet energy scale and resolution, and pileup have little effect. This is because the method used to derive the misassignment probabilities is based on templates for the lepton-jet invariant mass obtained from control samples in data. Other sources, which might affect the contribution from top-quark decays and from initial- and final-state radiation jets to the final sample, are evaluated using samples where the QCD factorisation and renormalisation scales and the jet-parton matching scales are varied. In the pseudo-experiments the standard $t\bar{t}$ sample is substituted by each of these samples and the process is repeated.

This bias is then used to shift the measured misassignment probabilities. The likelihood fit of the data is repeated with the modified values. The difference with respect to the nominal result is taken as the systematic uncertainty. The same procedure is applied to evaluate the uncertainty on the misidentification probability for non-b jets.

The final uncertainty is dominated by factors which tend to increase the contamination of background or alter the jet environment. The main uncertainties are the factorization scale, and to a smaller extent, the jet-parton matching with relative uncertainties on the scale factor of 2.3% and 1.4% respectively, for the CSVL operating point. The second-largest uncertainty arises from the 1.5% uncertainty on the light-parton jet tagging efficiency.

6.6 Efficiency measurement from a b-enriched jet sample

In this method, the b-jet tagging efficiency is measured from a sample enriched with b jets (bSample) in lepton+jets events. The contamination of this sample due to light-parton jets is estimated from data and subtracted.

In order to select the correct jets originating from the decay of the top quarks, a χ^2 is calculated for each jet-parton combination based on the masses of the reconstructed W boson m_{qq} and the hadronically decaying top quark m_{bqq} :

$$\chi^2 = \left(\frac{m_{bqq} - m_t}{\sigma_t} \right)^2 + \left(\frac{m_{qq} - m_W}{\sigma_W} \right)^2. \quad (18)$$

The mean masses and widths are obtained from the $t\bar{t}$ simulation using a Gaussian fit to the mass distributions of the combination with the correct jet-to-quark assignment. The mean and width of the reconstructed top-quark mass distribution are $172.5 \text{ GeV}/c^2$ and $16.3 \text{ GeV}/c^2$, respectively. The mean and width of the reconstructed W-boson distribution are $82.9 \text{ GeV}/c^2$ and $9.5 \text{ GeV}/c^2$, respectively. Using the four leading jets, with transverse momenta above $30 \text{ GeV}/c$, there are 12 combinations to pair the four reconstructed jets with the quarks from $t\bar{t}$ decay. The combination with the lowest χ^2 is selected to represent the event topology. The event is rejected if the lowest χ^2 is above 90.

A generic b-candidate sample is constructed by taking the jet assigned to the lepton. This sample is further subdivided into b-enriched and b-depleted subsamples by using the invariant mass of that jet and the muon (called the jet-muon mass, $m_{\mu j}$). The distribution of this variable is shown in Fig. 16. For the b-enriched subsample, the jet-muon mass is required to be in the

range $80 < m_{\mu j} < 150 \text{ GeV}/c^2$. For the b-depleted subsample the jet-muon mass is required to be in the range $150 < m_{\mu j} < 250 \text{ GeV}/c^2$. Based on the simulation, the purities of the two subsamples are 45% and 16%, respectively.

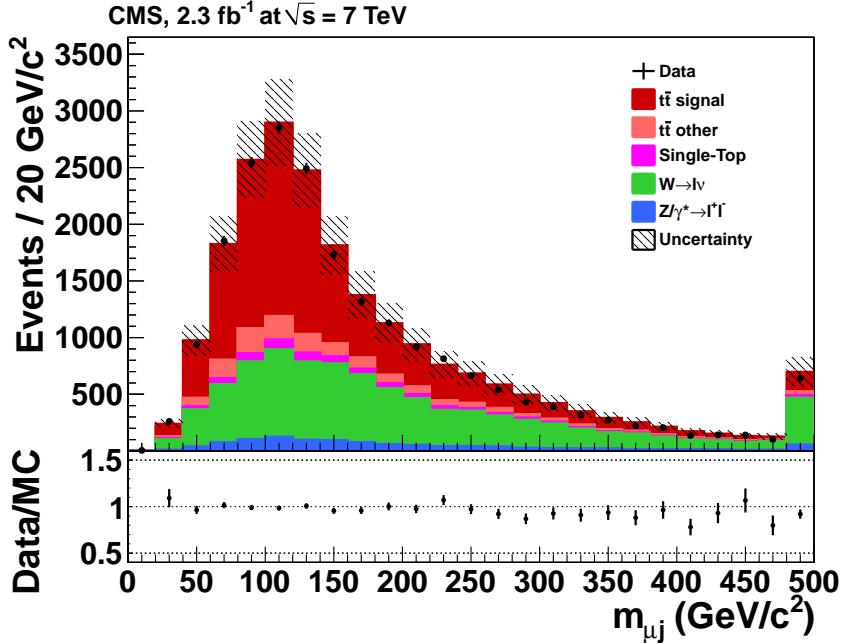

Figure 16: Distribution of the jet-muon mass in the data (filled circles) and the simulation (solid histograms). The simulated distribution is normalized to an integrated luminosity of 2.3 fb^{-1} . The component “ $t\bar{t}$ signal” stands for the lepton+jet events. The component “ $t\bar{t}$ other” contains the events in all other decay channels. The hatched area corresponds to the combined statistical and systematic uncertainty. Overflow entries are added to the last bin.

The distribution of the discriminators of the taggers for true b jets, $\hat{\Delta}_b^{\text{enr}}$, is obtained by subtracting the discriminator distribution of the b-depleted subsample, Δ_b^{depl} from the discriminator distribution of the b-enriched subsample, Δ_b^{enr} :

$$\hat{\Delta}_b^{\text{enr}} = \Delta_b^{\text{enr}} - F \times \Delta_b^{\text{depl}}. \quad (19)$$

The factor F represents the ratio of the number of non-b jets in the b-enriched and b-depleted subsamples. It is measured from a background dominated sample composed mainly of light-flavour quark jets. This sample is obtained by using the jets attributed to the decay of the W boson and ensuring that they both fail the b-jet tagging requirements of the TCHEM operating point. Both jets are used to construct a jet-muon mass distribution, and the same subsamples are defined as for the signal sample. The purity of light-flavour quark jets is 92% in the region $80 < m_{\mu j} < 150 \text{ GeV}/c^2$ and 95% in the region $150 < m_{\mu j} < 250 \text{ GeV}/c^2$. To match the shape of the jet-muon mass distribution of this background sample to that of the signal sample, the jets in the background sample are reweighted according to the (p_T, η) of the signal sample. After this reweighting, the two samples have similar jet-muon mass distribution. The factor F is taken as the ratio of the number of events in the $80 < m_{\mu j} < 150 \text{ GeV}/c^2$ and the $150 < m_{\mu j} < 250 \text{ GeV}/c^2$ regions in the background sample, and is found to be 1.16 ± 0.02 .

A small correlation between the jet-muon mass and the discriminators has to be corrected for. This correlation is attributed to the correlation between the transverse momentum of the jet

and the jet-muon mass. This correlation distorts the distribution of the discriminants of the b-jet tagging algorithms in the b-depleted subsample with respect to the distribution of the non-b jets in the b-enhanced subsample. This effect is corrected by reweighting the jets in the b-depleted subsample according to the transverse momentum distribution of the jets in the b-enhanced subsample.

The systematic uncertainties for the b-jet tagging efficiency and the scale factors are the absolute differences between the nominal simulation sample and the sample with modified parameters. Additionally, a systematic uncertainty is assigned based on tests of the method in simulation. The tests show no bias in the method with an uncertainty driven by statistical uncertainties on available samples. For the CSVL operating point, the relative uncertainty is 3.1%. The jet energy scale and resolution have a small contribution from the change in the mean masses and widths used for the χ^2 . For the CSVL operating point, the relative uncertainties on the scale factor are 1.4% and 2.2%, respectively. A small uncertainty of 0.5% is due to the choice of the boundaries of the b-depleted region. The high tail of the jet-muon mass distribution is composed mainly of background events and wrongly combined jets that do not reflect the kinematics of the signal events. The effect of imposing an upper limit on the region is assessed by varying the boundary between 200 and 300 GeV/c^2 .

7 Efficiency measurement results

7.1 Results from multijet events

The methods described in Section 5 cover a large range of jet transverse momenta. The PtRel and the System8 methods provide precise measurements for the lower part of the spectrum. The IP3D and the LT methods have been designed for high jet p_T . The measured data/MC scale factors are given in Table 7 for jets with low p_T from 80 to 120 GeV/c , and in Table 8 for jets with high p_T , from 160 to 320 GeV/c . In these ranges the methods give compatible results within the quoted uncertainties. While some of the methods measure the efficiencies and scale factors only for muon jets, and not inclusive b jets, simulation studies have shown that the difference in tagging efficiencies between the two are only a few percent. We assume that these small differences have no significant effect on the scale factors, which are relative data/MC measurements.

The results have been combined to provide the best measurements of the data/MC scale factors for $30 < p_T < 670 \text{ GeV}/c$. For each jet p_T range the most precise results have been used: the PtRel and System8 methods for $p_T < 120 \text{ GeV}/c$, the IP3D method for $p_T > 120 \text{ GeV}/c$ and the LT method for the full momentum range.

The combination is based on a weighted mean of the scale factors in each jet p_T bin [45]. However, there are a significant number of jets from QCD dijet and multijet events (with at least one muon associated to a jet) which are shared between the methods. The shared fraction of jets varies with jet p_T . Typical values are 10–25% between the LT and PtRel/IP3D methods, 40–50% between the PtRel and System8 methods, and 20–50% between the System8 and LT methods. This overlap has been taken into account in the combination.

Several sources of systematic uncertainties are common for all methods: the effects due to pileup, gluon splitting, and the selection criteria for muons. The muon PtRel and IP3D methods have the same sensitivity to the choice of the away-jet tagger. The corresponding uncertainties were assumed to be fully correlated or anticorrelated according to the sign of the variations observed for the different methods. All other systematic effects are specific to individual methods

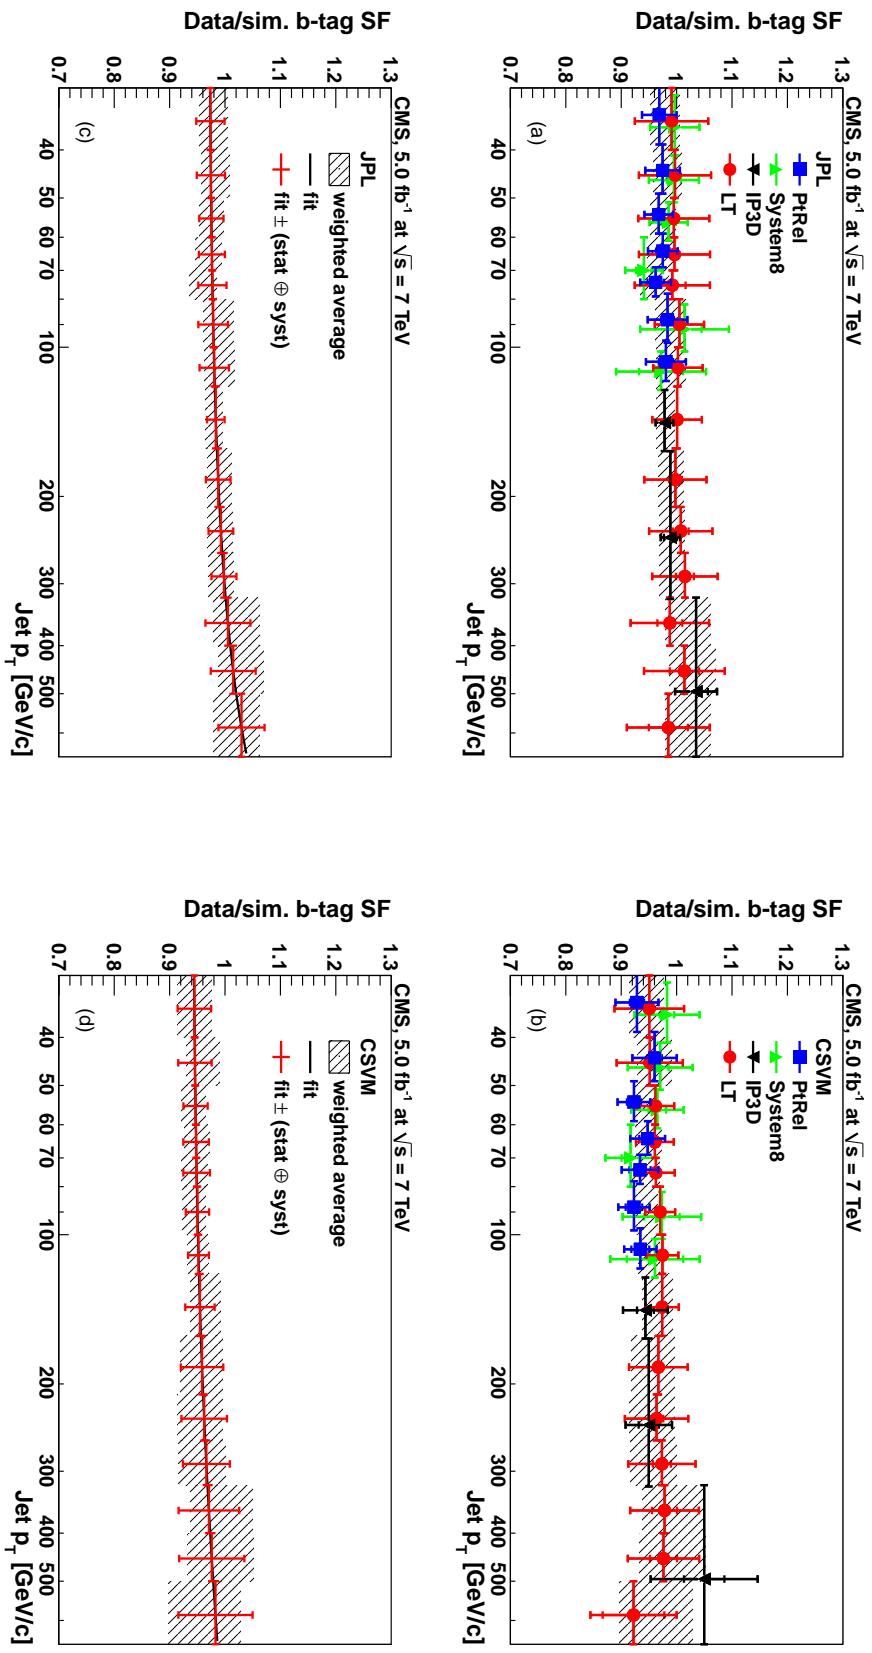

Figure 17: Individual and combined measurements of the ratio of the b-jet tagging efficiencies of the data to that in simulation for the (a, c) JP_L and (b, d) CSV taggers. Figures (a) and (b) show the individual measurements from the muon p_T^{rel} (“PtRel”), System8 (“System8”), muon IP (“IP3D”), and lifetime tagger (“LT”) methods. The inner and outer error bars indicate the statistical and the combined uncertainties, respectively. The hatched areas represent the combined measurements. In figures (c) and (d) the combined measurements have been parameterized by functions of the form $SF_b(p_T) = \alpha(1 + \beta p_T)/(1 + \gamma p_T)$. The error bars attached to the function have the same size as the uncertainties from the combined measurement in each bin.

Table 7: Data/MC scale factors SF_b as measured using the PtRel, System8, and LT methods and their combination. Results are given for jet p_T between 80 and 120 GeV/ c . The first uncertainty on SF_b is statistical and the second is systematic. For the combination the total uncertainty is quoted.

and have been treated as uncorrelated. A conservative value for the uncertainty is used if the χ^2 from the fit exceeds the number of degrees of freedom, in which case the uncertainty is scaled by the square root of the normalised χ^2 . Summaries for the individual and combined scale factor measurements for the JPL and the CSVM taggers are shown in Fig. 17. Also shown are the parameterizations of the combined scale factor of the form $SF_b(p_T) = \alpha(1 + \beta p_T)/(1 + \gamma p_T)$. Combined values for a low and a high jet p_T range are shown in the right hand columns of Tables 7 and 8, respectively.

7.2 Results from $t\bar{t}$ events

The statistical properties of the four methods presented in Sections 6.3 to 6.6 have been studied using ensembles of pseudo-experiments based on the expected numbers of signal and background events. The distributions of the estimated values and their uncertainties show that the methods are unbiased. This is shown by the pull distributions, which have mean values close to zero and standard deviations close to one.

The scale factors $SF_b = \varepsilon_b^{\text{meas}} / \varepsilon_b^{\text{MC}}$ measured with the different algorithms are shown in Table 9 using data with an integrated luminosity of 2.3 fb^{-1} . The scale factors were stable over the whole data-taking period and can be applied to the full dataset. The measured b-jet tagging efficiencies and scale factors for the CSV algorithm are shown in Fig. 18.

The PLR and FTC methods are used to calculate a combined scale factor for use in analyses, by taking the weighted mean of the scale factors from each method. The two methods are chosen because each has the smallest uncertainty among the analyses in its respective decay channel. By choosing one analysis in the dilepton channel and one in the lepton+jets channel, there is no statistical correlation between the two measurements as the samples are mutually exclusive. Based on the statistical and systematic uncertainties of the PLR and FTC methods, the uncertainty of the resulting scale factor is ± 0.03 for all operating points.

Table 8: Data/MC scale factors SF_b as measured using the IP3D and LT methods and their combination. Results are given for jet p_T between 160 and 320 GeV/c. The first uncertainty on SF_b is statistical and the second is systematic. For the combination the total uncertainty is quoted.

A continuous function for the scale factors is required in physics analyses that use b-jet tagging discriminators with multivariate methods. The function is obtained from a linear fit to the distribution of the scale factors measured with the FTC method. This is offset vertically to match the weighted mean of the medium operating point, as illustrated in Fig. 19.

7.3 Comparison of results

The p_T -dependent scale factors measured in dijet and multijet events have been compared by reweighted them to match the jet p_T spectrum observed in $t\bar{t}$ events. The results are shown in Table 10 and are in good agreement with each other. This justifies the assumption that the scale factors for the muon jets and inclusive jets are compatible.

8 Misidentification probability measurement

The measurement of the misidentification probability for light-parton jets relies on the definition of inverted tagging algorithms, selecting non-b jets using the same variables and techniques as the standard versions. These “negative taggers” can be used in the same way as the regular b-jet tagging algorithms both in data and in the simulation. As the negative-tagged jets are enriched in light flavours, the misidentification probability can be measured from data, with the simulation used to extract a correction factor.

The misidentification probability is evaluated from tracks with a negative impact parameter or from secondary vertices with a negative decay length (see Section 4). When a negative tagger is applied to jets of any flavour, the corresponding tagging efficiency is denoted “negative tag rate”. The negative and positive b-jet tagging discriminator distributions in data are compared with the simulation in Fig. 20. The events are selected by requiring jet triggers with a p_T threshold of 30 GeV/c, corresponding to an average p_T over all jets in the events of 44 GeV/c. For all b-jet tagging algorithms, the data and simulation are found to be in agreement to within about

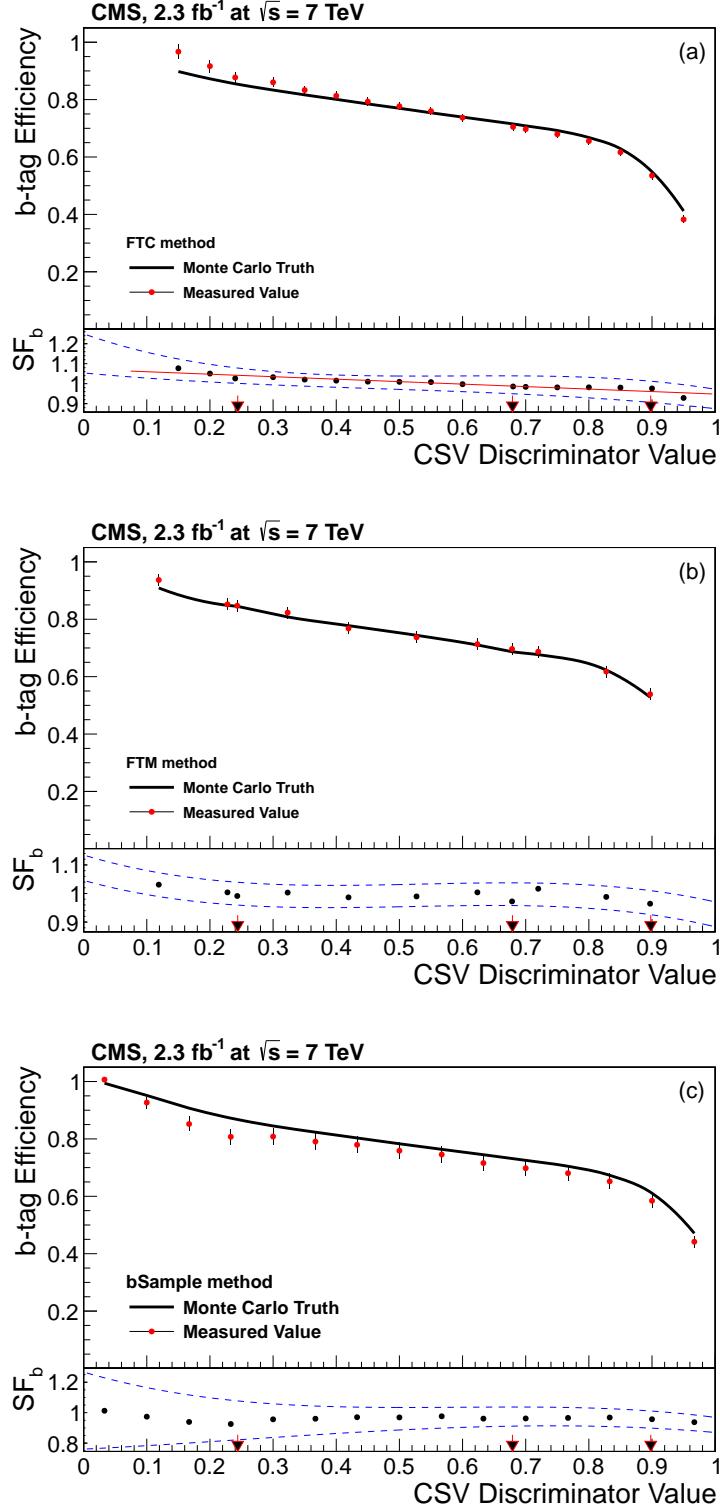

Figure 18: Measured b-jet tagging efficiency as a function of the flavour discriminator threshold for the CSV algorithm, measured with the (a) FTC method, (b) FTM method and (c) bSample method. The absolute b-jet tagging efficiencies measured from data and predicted from simulation are shown in the upper histograms of each panel. The scale factors SF_b are shown in the lower histogram, where the blue dashed lines represent the combined statistical and systematic uncertainty. The arrows indicate the standard operating points. For the FTC method, the red line represents a linear function fitted on the distribution of the scale factors.

Table 9: The scale factors SF_b as measured using the PLR, FTC, FTM and bSample methods, and the weighted mean (WM). The uncertainties are the combined statistical and systematic uncertainty.

$\pm 20\%$. Similar results are found for a sample of events selected by requiring jet triggers with a p_T threshold of $300\text{ GeV}/c$, in which the average p_T is $213\text{ GeV}/c$. Depending on the prescales applied, the data correspond to an integrated luminosity of up to 5.0 fb^{-1} .

The misidentification probability is evaluated as:

$$\varepsilon_{\text{data}}^{\text{misid}} = \varepsilon_{\text{data}}^- \cdot R_{\text{light}}, \quad (20)$$

where $\varepsilon_{\text{data}}^-$ is the negative tag rate as measured in jet data, defined as the fraction of jets that are negatively tagged. $R_{\text{light}} = \varepsilon_{\text{MC}}^{\text{misid}} / \varepsilon_{\text{MC}}^-$, a correction factor taken from simulation, is the ratio of the misidentification probability for light-parton jets to the negative tag rate for jets of all flavours in the simulation.

The rate $\varepsilon_{\text{data}}^-$ depends on the numbers of c and b quarks in the negative-tagged jets (which tend to decrease R_{light}), on the residual differences between light-flavour quark and gluon jets, the number of tracks from other displaced processes (such as K_S^0 and Λ decays, and interactions in the detector material), and mismeasured tracks (which tend to increase R_{light}). Due to these contributions the simulation predicts ranges of R_{light} , for the different algorithms and jet p_T values, of about 1.1 to 1.4, 1 to 2, and 1 to 4, for the loose, medium, and tight operating points, respectively.

To compare the measured misidentification probability to that predicted by the simulation, a scale factor SF_{light} is defined:

$$SF_{\text{light}} = \varepsilon_{\text{data}}^{\text{misid}} / \varepsilon_{\text{MC}}^{\text{misid}}. \quad (21)$$

The following systematic effects on the misidentification probability based on negative tags are considered:

- **b and c fractions:** The fraction of b-flavour jets has been measured in CMS to agree with the simulation within a $\pm 20\%$ uncertainty [46]. A $\pm 20\%$ uncertainty is conservatively estimated for the overall fraction of b and c jets. The b- and c-flavour

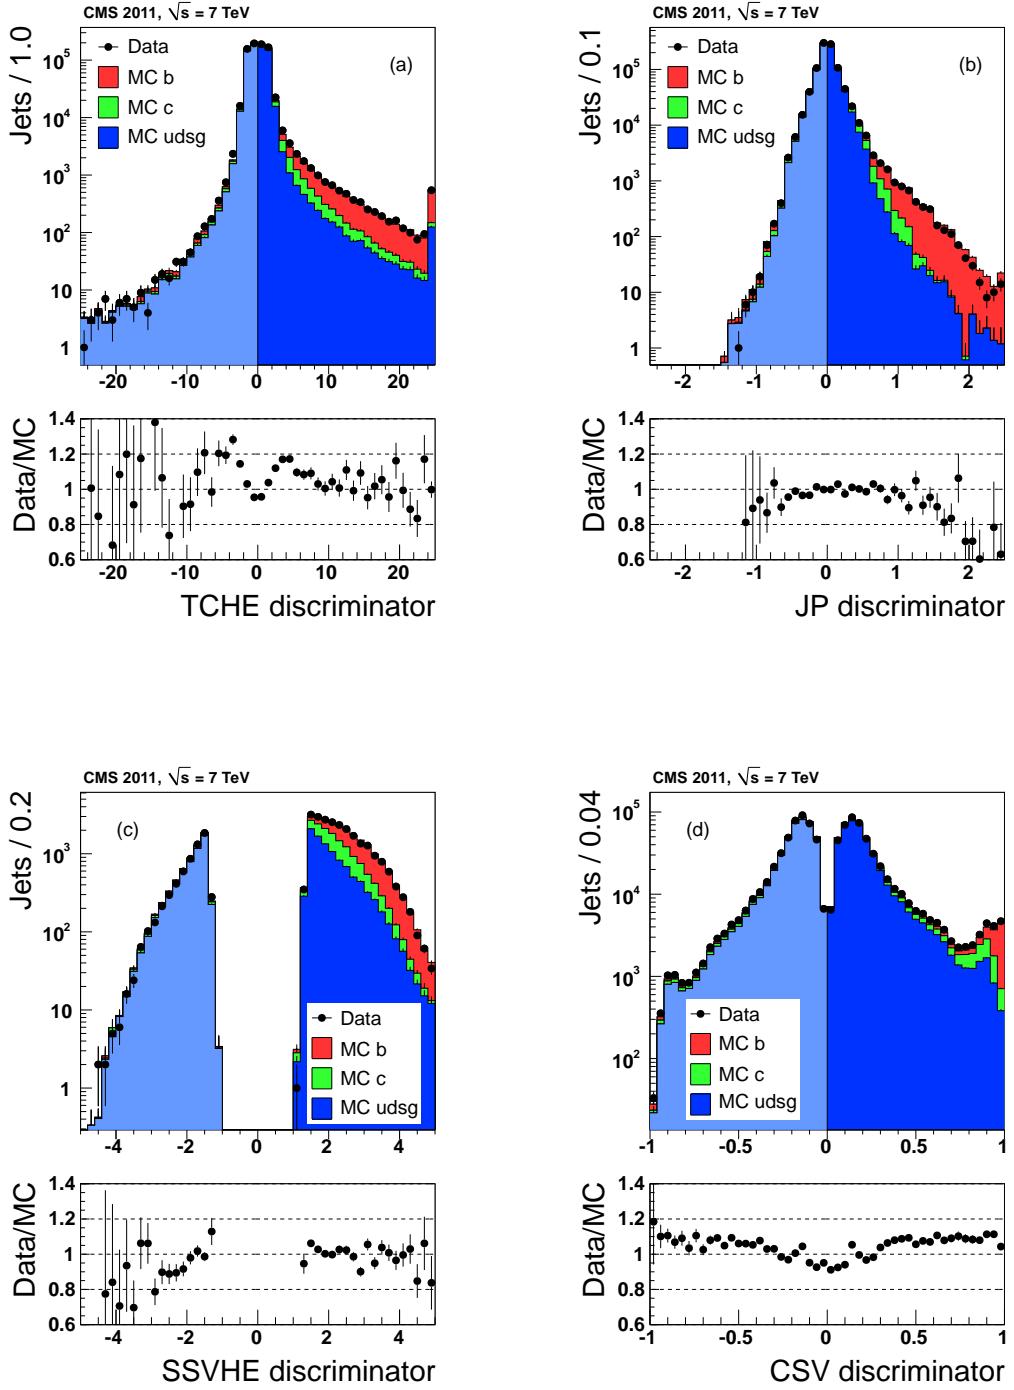

Figure 20: Signed b-jet tagging discriminators in data (dots) and simulation for light-parton jets (blue histogram, with a lighter colour for the negative discriminators), c jets (green histogram), and b jets (red histogram) for the (a) TCHE, (b) JP, (c) SSVHE, and (d) CSV algorithms. A jet-trigger p_T threshold of 30 GeV/c is required for both data and simulation. The simulation is normalized to the number of entries in the data. Underflow and overflow entries are added to the first and last bins, respectively.

fraction is varied in the QCD multijet simulation, from which a systematic uncertainty on R_{light} is inferred.

- **Gluon fraction:** This affects both the misidentification probability in simulation and the overall negative tag rates. The average fraction of gluon jets depends on the details of the parton density and hadronization functions used in the simulation. An uncertainty of $\pm 20\%$ is extracted from the comparison of simulation with data [47].
- **Long-lived K_S^0 and Λ decays:** The amount of reconstructed K_S^0 and Λ are found to be larger in the data than in the simulation [48]. To estimate the uncertainty on R_{light} due to the K_S^0 and Λ contribution, the simulated jets are reweighted by factors of 1.3 ± 0.3 and 1.5 ± 0.5 , respectively, in order to match the observed yield of K_S^0 and Λ in the data. The quoted uncertainties on the factors account for the p_T dependence. The yield is varied accordingly and the inferred variation on R_{light} is taken as a systematic uncertainty.
- **Photon conversion and nuclear interactions:** The rate of secondary interactions in the pixel detector layers has been measured with $\pm 5\%$ precision [29, 49]. The corresponding variation implies a systematic uncertainty on R_{light} .
- **Mismeasured tracks:** According to the simulation, jets with a reconstructed track not associated with a genuine charged particle also present an excess of positive over negative tags. To correct for residual mismeasurement effects, a $\pm 50\%$ variation on this contribution is taken into account in the systematic uncertainty on R_{light} .
- **Sign flip:** Small differences in the angle between a track and the jet axis can lead to a change of the sign of the impact parameter (“sign flip”) and modify the negative tag rate. In order to quantify this effect the ratio of the number of negative to positive tagged jets is computed in a muon jet sample similar to the one described in Section 5, with a larger than 80% b purity. Data and simulation are found to be in good agreement. From the statistical uncertainty on the comparison, the absolute uncertainty on this ratio is estimated as 2%, 1%, and 0.5% for loose, medium, and tight operating points, respectively. This sign flip uncertainty can be translated into a systematic uncertainty on R_{light} .
- **Pileup:** The misidentification probability depends on the pileup model used in the simulation. The simulated events are reweighted in order to match the pileup rate in the data. Differences between R_{light} values obtained for different running periods are used to estimate the systematic uncertainty, which is about $\pm 1\%$ for all taggers.
- **Event sample:** Physics analyses use jets from different event topologies. For a given jet p_T , the misidentification probability is different for the leading jet or if there are other jets with higher p_T values in the same event. Measured misidentification scale factors for leading and subleading jets have a dispersion of about 7%. In addition, misidentification scale factors vary by 2–7%, depending on the tagger, for different running periods. These two uncertainties are added in quadrature to account for an uncertainty due to sample dependence. This is the dominant contribution to the overall systematic uncertainty on the misidentification probability.

The systematic uncertainties are detailed in Table 11 for the various algorithms and for the example of the medium operating points in the jet p_T range between 80 and 120 GeV/ c .

The measured misidentification probabilities and data/MC scale factors are presented in Figs. 21 and 22 as a function of the jet p_T for the JPL and CSVM taggers. For a jet p_T of about 80 GeV/ c the misidentification probabilities are close to 10% and 1% for the loose (JPL) and medium (CSVM)

Table 11: Relative systematic uncertainties on SF_{light} for jet p_T in the range 80–120 GeV/ c . The columns correspond to the different sources of systematics in the order described in the text.

selections, respectively. Both algorithms show an increase of the misidentification probability with jet p_T that can be explained by the higher track densities in collimated jets. The simulation reproduces this dependence to a large extent. The observed scale factors are close to one with a decrease of $\sim 10\%$ toward the highest jet p_T . The misidentification probabilities measured with data and the data/MC scale factors are given in Table 12 for jets with p_T between 80 and 120 GeV/ c .

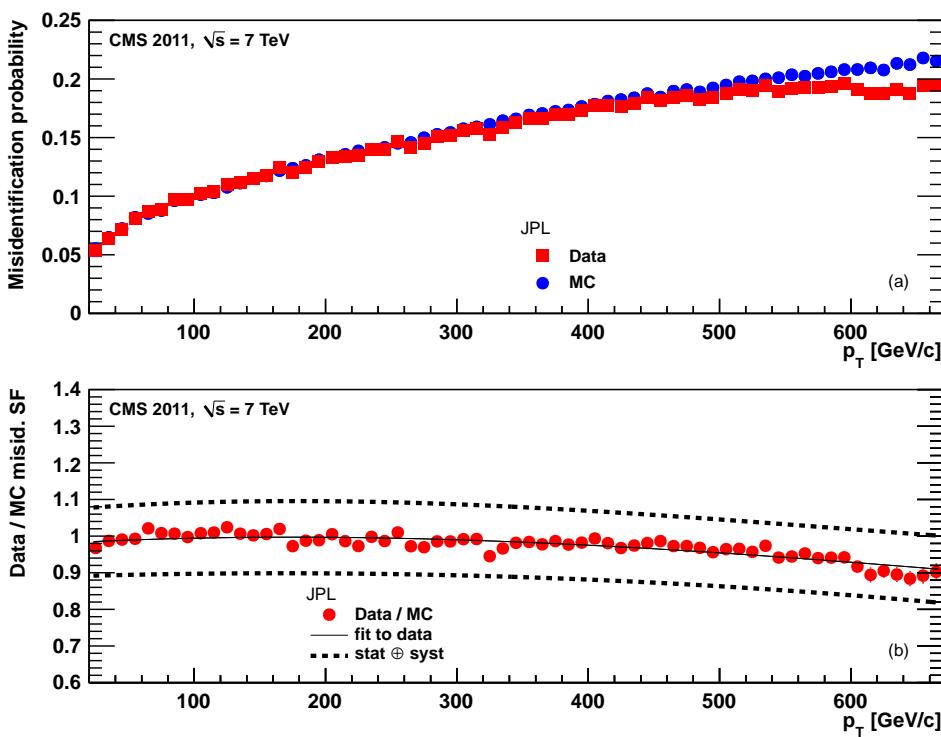

Figure 21: For the JPL tagger: (a) misidentification probability in data (red squares) and simulation (blue dots); (b) scale factor for the misidentification probability. The last p_T bin in each plot includes all jets with $p_T > 670 \text{ GeV}/c$. The solid curve is the result of a polynomial fit to the data points. The dashed curves represent the overall statistical and systematic uncertainties on the measurements.

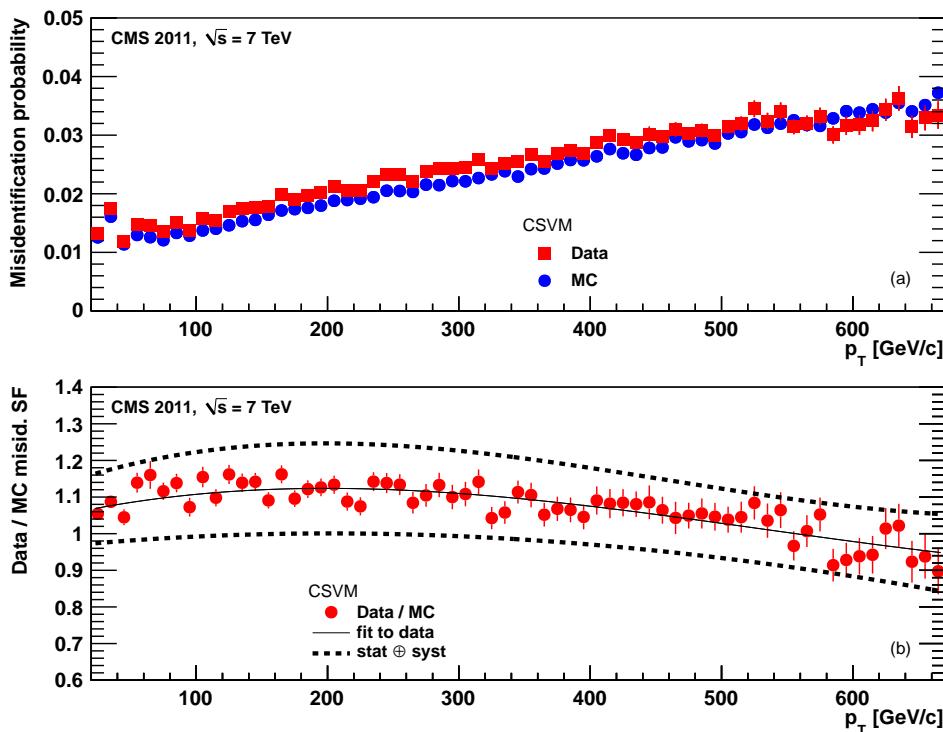

Figure 22: Same as Fig. 21 but for the CSVM tagger.

9 Conclusions

The CMS collaboration has developed a variety of algorithms that are used to identify jets that arise from the hadronization of bottom quarks. Early analyses relied on simple and robust techniques, based on the second or third highest impact parameter significance of the tracks associated to a jet, or the flight distance measured using a reconstructed secondary vertex. More recent analyses use algorithms with better performance that define a powerful discriminant from the combination of several variables. The use of these more advanced algorithms is made possible by the high degree of agreement achieved between data and simulation, and by the robustness of the algorithms against variations in the running conditions.

The algorithms provide selections at several operating points. The efficiencies of the algorithms at these operating points have been measured with a number of methods using multijet and $t\bar{t}$ events. A differential measurement of the efficiency as a function of jet p_T , from 30 to 670 GeV/ c , has been carried out with the multijet sample. This information is used in analyses that require knowledge of the performance of b-jet tagging over a wide range of transverse momenta. The information is also helpful for analyses such as the measurement of the $t\bar{t}$ cross section in order to avoid the strong correlations that can occur if the efficiencies are inferred from the $t\bar{t}$ event sample itself.

The $t\bar{t}$ sample provides inclusive results, which are suitable for measurements of top-quark properties and for the analysis of standard model processes with similar jet momentum spectra and multiplicities. The misidentification probability, that a light-parton jet is mistaken as a b-quark jet, has been measured by applying inverted tagging algorithms to the multijet events.

The most effective algorithm is the Combined Secondary Vertex tagger. Using a loose selection, CMS achieves b-jet tagging efficiencies of about 85%, for a light-parton misidentification probability of 10%. This selection is suited for $t\bar{t}$ analyses. In analyses requiring higher b-jet purity, such as searches for supersymmetric particles, approximately 70% b-jet tagging efficiency is achieved, for a light-parton misidentification probability of only 1.5%. These values apply for jet transverse momenta typically observed in $t\bar{t}$ events.

The measured b-jet tagging performance is quantified and implemented in CMS analyses by using scale factor corrections to the MC simulation. These scale factors have been used extensively to enable studies over a wide range of event topologies that would otherwise not be possible due to limited statistics. The scale factors for the b-jet tagging efficiencies are measured with uncertainties of 2–4%, and 3–8%, in the jet p_T range 30–320 GeV/ c and 320–670 GeV/ c respectively. The maximum deviation of these scale factors from unity is approximately 10%. The scale factors for light-parton jet misidentification probabilities are measured to a precision of 8–17% over the full p_T range, and differ from unity by at most 25%.

The b-jet identification techniques discussed in this paper have been used in more than 40 analyses published by CMS, including measurements of top-quark properties, the Higgs boson, and searches for signals of physics beyond the standard model. The reduction of the uncertainties on the b-jet tagging scale factors has enabled the CMS experiment to decrease the light-parton background to unprecedented levels while maintaining high b-jet tagging efficiency for a wide range of processes containing heavy-flavour jets.

Acknowledgements

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC machine. We thank the technical and administrative staff at CERN and

other CMS institutes. †: Deceased

1: Also at Vienna University of Technology, Vienna, Austria

2: Also at National Institute of Chemical Physics and Biophysics, Tallinn, Estonia

3: Also at Universidade Federal do ABC, Santo Andre, Brazil

4: Also at California Institute of Technology, Pasadena, USA

- 5: Also at CERN, European Organization for Nuclear Research, Geneva, Switzerland
- 6: Also at Laboratoire Leprince-Ringuet, Ecole Polytechnique, IN2P3-CNRS, Palaiseau, France
- 7: Also at Suez Canal University, Suez, Egypt
- 8: Also at Zewail City of Science and Technology, Zewail, Egypt
- 9: Also at Cairo University, Cairo, Egypt
- 10: Also at Fayoum University, El-Fayoum, Egypt
- 11: Also at British University in Egypt, Cairo, Egypt
- 12: Now at Ain Shams University, Cairo, Egypt
- 13: Also at National Centre for Nuclear Research, Swierk, Poland
- 14: Also at Université de Haute-Alsace, Mulhouse, France
- 15: Now at Joint Institute for Nuclear Research, Dubna, Russia
- 16: Also at Moscow State University, Moscow, Russia
- 17: Also at Brandenburg University of Technology, Cottbus, Germany
- 18: Also at Institute of Nuclear Research ATOMKI, Debrecen, Hungary
- 19: Also at Eötvös Loránd University, Budapest, Hungary
- 20: Also at Tata Institute of Fundamental Research - HECR, Mumbai, India
- 21: Also at University of Visva-Bharati, Santiniketan, India
- 22: Also at Sharif University of Technology, Tehran, Iran
- 23: Also at Isfahan University of Technology, Isfahan, Iran
- 24: Also at Plasma Physics Research Center, Science and Research Branch, Islamic Azad University, Tehran, Iran
- 25: Also at Facoltà Ingegneria, Università di Roma, Roma, Italy
- 26: Also at Università della Basilicata, Potenza, Italy
- 27: Also at Università degli Studi Guglielmo Marconi, Roma, Italy
- 28: Also at Università degli Studi di Siena, Siena, Italy
- 29: Also at University of Bucharest, Faculty of Physics, Bucuresti-Magurele, Romania
- 30: Also at INFN Sezione di Padova; Università di Padova; Università di Trento (Trento), Padova, Italy
- 31: Also at Faculty of Physics of University of Belgrade, Belgrade, Serbia
- 32: Also at University of California, Los Angeles, Los Angeles, USA
- 33: Also at Scuola Normale e Sezione dell'INFN, Pisa, Italy
- 34: Also at INFN Sezione di Roma; Università di Roma, Roma, Italy
- 35: Also at University of Athens, Athens, Greece
- 36: Also at Rutherford Appleton Laboratory, Didcot, United Kingdom
- 37: Also at The University of Kansas, Lawrence, USA
- 38: Also at Paul Scherrer Institut, Villigen, Switzerland
- 39: Also at Institute for Theoretical and Experimental Physics, Moscow, Russia
- 40: Also at Gaziosmanpasa University, Tokat, Turkey
- 41: Also at Adiyaman University, Adiyaman, Turkey
- 42: Also at Izmir Institute of Technology, Izmir, Turkey
- 43: Also at The University of Iowa, Iowa City, USA
- 44: Also at Mersin University, Mersin, Turkey
- 45: Also at Ozyegin University, Istanbul, Turkey
- 46: Also at Kafkas University, Kars, Turkey
- 47: Also at Suleyman Demirel University, Isparta, Turkey
- 48: Also at Ege University, Izmir, Turkey
- 49: Also at School of Physics and Astronomy, University of Southampton, Southampton, United Kingdom
- 50: Also at INFN Sezione di Perugia; Università di Perugia, Perugia, Italy

- 51: Also at University of Sydney, Sydney, Australia
- 52: Also at Utah Valley University, Orem, USA
- 53: Also at Institute for Nuclear Research, Moscow, Russia
- 54: Also at University of Belgrade, Faculty of Physics and Vinca Institute of Nuclear Sciences, Belgrade, Serbia
- 55: Also at Argonne National Laboratory, Argonne, USA
- 56: Also at Erzincan University, Erzincan, Turkey
- 57: Also at KFKI Research Institute for Particle and Nuclear Physics, Budapest, Hungary
- 58: Also at Kyungpook National University, Daegu, Korea
